**Figure 9** Negative-ion static SIMS spectra over a 50–250  $m/z$  range for (A) PMMA (monomer repeat mass ( $M$ ) of 100  $m/z$ ) and (B) PEMA (monomer repeat mass ( $M$ ) of 114). Polymers containing electronegative heteroatoms, such as oxygen in this case, often yield negative-ion spectra rich in information that can uniquely identify the polymer being analyzed.

**Laser ionization** The identification of unknown inclusions in a variety of matrices is very important in an industrial environment. One method used to analyze these unwanted small ( $\sim 1\text{--}50\text{ }\mu\text{m}$  diameter) inclusions is laser desorption/ionization mass analysis, also known as laser microprobe mass spectrometry and laser microprobe analysis. Trade names used are LIMA (laser ionization mass analyzer) and LAMMA (laser microprobe mass analysis). A variable-power laser is focused on to the inclusion. As discussed above, the desorption/ionization process is very sensitive to the power density of the laser at the sample surface. Firing the laser with an appropriate power setting generates ions containing information about the inclusion, which are then mass-analyzed using TOF-MS.

The spectra obtained from small ( $\sim 10\text{ }\mu\text{m}$  diameter) particles of unknown composition in a polymer matrix are shown in **Figure 8**. These spectra were obtained on a LIMA (Cambridge Mass Spectrometry, UK), which incorporates a reflecting TOF. It was found that all of the particles contained iron, titanium, aluminum, silicon, sodium, potassium, calcium, magnesium, carbon, and oxygen. The four most significant elements present were iron, titanium, carbon, and oxygen. Although this technique is semiquantitative at best, the observed distribution of these elements is consistent with that associated with a low-grade oxidized carbon steel and not from a stainless steel. The titanium level was abnormally high and was believed to be from paint, which contains high levels of  $\text{TiO}_2$ . Therefore, it appears likely that the unknown particles are from painted-over rust deposits that are easily dislodged and settle in the polymer product.

**Static secondary ion mass spectrometry (SIMS) of polymers** Static SIMS is a technique that obtains a mass spectrum of the upper 2 nm of a surface. Knowledge about surfaces is very important in studies of adhesion, corrosion, catalytic activity, biological compatibility, etc. By limiting the total primary ion dose from a primary ion beam to less than  $10^{13}$  ions per  $\text{cm}^2$ , each primary ion interacts with a sample that has not been damaged by previous primary ion impacts. In this way less than 1% of the total surface will be damaged by primary ion impacts.

Static SIMS is capable of obtaining very reproducible fingerprint spectra from bulk polymer surfaces. For example, static SIMS can easily distinguish between poly(methyl methacrylate) (PMMA) and the structurally similar poly(ethyl methacrylate) (PEMA) (**Figure 9**) based upon the unique negative ion fragmentation pattern obtained from each polymer. PEMA has a monomer repeat unit mass of 114 amu;

this is 14 amu heavier than that for PMMA, which is 100 amu. Thus, many of the fragments observed in the PMMA spectrum have corresponding fragments at masses 14 amu higher in the PEMA spectrum.

These spectra were obtained from a Poschenrieder TOF instrument equipped with a 30 keV Ga liquid-metal ion gun. The area analyzed was  $\sim 300 \times 300\text{ }\mu\text{m}$  using a total ion dose of  $\sim 10^{12}$  ions per  $\text{cm}^2$ .

It is interesting to note that from each pulse of the ion gun  $\sim 300$  gallium ions strike a spot less than 100 nm in diameter on the sample. Secondary ion yields for organic materials are typically between  $10^{-3}$  and  $10^{-4}$  secondary ions per primary ion impact. Thus, only a few fragment ions from the polymer surface are produced per pulse. The high transmission of the TOF allows for  $\sim 50\%$  of these secondary ions to be mass-analyzed. To obtain the final mass spectrum, hundreds of thousands of individual mass spectra are integrated. With TOF-MS, usable static SIMS mass spectra from areas as small as  $25 \times 25\text{ }\mu\text{m}$  can be obtained from polymer surfaces.

### Introduction

The technique of selected ion monitoring (SIM) (not to be confused with secondary ion mass spectrometry, SIMS), also referred to as selected ion recording or multiple ion detection (MID), is the use of a mass spectrometer to record the intensities of a limited number of ions. This allows the instrument to dwell for a greater proportion of the analysis time on those mass-to-charge ratios of greatest significance in the mass spectrum of a compound of interest. The major application of the technique is in organic mass spectrometry (MS), where SIM data are typically acquired using instruments coupled to chromatographic inlet systems, allowing the qualitative or quantitative determination of organic compounds at extremely low concentrations. Inorganic mass spectrometry (inductively coupled plasma-MS and thermal ionization MS) and stable isotope ratio mass spectrometry (IRMS) also, typically, record only the intensity of selected ions. The term SIM is, however, generally only applied to organic MS.

In an early report (1966), the accelerating voltage of a magnetic sector instrument was rapidly switched by an 'accelerating voltage alternator' in order to focus the ions of interest onto the detector slit. Combined gas chromatography-mass spectrometry (GC-MS) was used to monitor the elution, from a packed column GC, of trimethylsilyl glucose and an internal standard comprising the closely eluting deuterated ( $d_7$ ) analog (**Figure 1**). The chromatographic peaks corresponding to the deuterated compound were observed at a slightly earlier retention time than the corresponding nondeuterated compound. Since the analyte and internal standard had very similar chemical and chromatographic properties, quantitation was achieved from a simple ratio of the two isotopomers. The fundamental principles

of the technique remain unchanged to the present day.

The identification of a compound by means of MS is normally achieved by recording the full mass spectrum of the compound of interest (full data collection). To identify a compound as unambiguously as possible, using a single analytical technique, this acquired spectrum may be compared either with the mass spectrum of an authentic standard or with a library spectrum. Authorities concur that 10 complete scans of the mass analyzer are typically required to characterize a compound. In practice, however, it is not always possible to acquire a full mass spectrum, either due to low sample concentration or matrix interference. During full data collection, the intensities of all mass-to-charge ratios, between selected mass limits, are recorded to produce a complete mass spectrum. The instrument scans through these masses spending a certain time recording the intensity of ions reaching the detector at each mass-to-charge ratio. The scanning cycle is then repeated, following a brief reset period. During this process, however, a proportion of the analysis time is used to monitor mass-to-charge regions in which no ions are present or ions that are of little or no diagnostic value or structural significance. In addition, the occurrence of certain ions is too ubiquitous to be of analytical value. The proportion of such ions may be considerable, and will depend on the analyte, the ionization process used, and other compounds present in the sample. The time available for scanning is limited; specifically only a restricted number of scans may be acquired during the elution of a chromatographic peak. This is especially true of modern chromatographic techniques, such as capillary GC (including 'fast GC') and capillary electrophoresis (CE), in which the chromatographic peakwidth may be less than a second. Using SIM, only a restricted number of ions are monitored; generally, those that are diagnostic for a particular compound or class of compounds. In this way, the proportion of time spent monitoring each of these ions may be substantially increased, leading to an improvement in sensitivity toward the compound

### Introduction

The technique of selected ion monitoring (SIM) (not to be confused with secondary ion mass spectrometry, SIMS), also referred to as selected ion recording or multiple ion detection (MID), is the use of a mass spectrometer to record the intensities of a limited number of ions. This allows the instrument to dwell for a greater proportion of the analysis time on those mass-to-charge ratios of greatest significance in the mass spectrum of a compound of interest. The major application of the technique is in organic mass spectrometry (MS), where SIM data are typically acquired using instruments coupled to chromatographic inlet systems, allowing the qualitative or quantitative determination of organic compounds at extremely low concentrations. Inorganic mass spectrometry (inductively coupled plasma-MS and thermal ionization MS) and stable isotope ratio mass spectrometry (IRMS) also, typically, record only the intensity of selected ions. The term SIM is, however, generally only applied to organic MS.

In an early report (1966), the accelerating voltage of a magnetic sector instrument was rapidly switched by an 'accelerating voltage alternator' in order to focus the ions of interest onto the detector slit. Combined gas chromatography-mass spectrometry (GC-MS) was used to monitor the elution, from a packed column GC, of trimethylsilyl glucose and an internal standard comprising the closely eluting deuterated ( $d_7$ ) analog (**Figure 1**). The chromatographic peaks corresponding to the deuterated compound were observed at a slightly earlier retention time than the corresponding nondeuterated compound. Since the analyte and internal standard had very similar chemical and chromatographic properties, quantitation was achieved from a simple ratio of the two isotopomers. The fundamental principles

of the technique remain unchanged to the present day.

The identification of a compound by means of MS is normally achieved by recording the full mass spectrum of the compound of interest (full data collection). To identify a compound as unambiguously as possible, using a single analytical technique, this acquired spectrum may be compared either with the mass spectrum of an authentic standard or with a library spectrum. Authorities concur that 10 complete scans of the mass analyzer are typically required to characterize a compound. In practice, however, it is not always possible to acquire a full mass spectrum, either due to low sample concentration or matrix interference. During full data collection, the intensities of all mass-to-charge ratios, between selected mass limits, are recorded to produce a complete mass spectrum. The instrument scans through these masses spending a certain time recording the intensity of ions reaching the detector at each mass-to-charge ratio. The scanning cycle is then repeated, following a brief reset period. During this process, however, a proportion of the analysis time is used to monitor mass-to-charge regions in which no ions are present or ions that are of little or no diagnostic value or structural significance. In addition, the occurrence of certain ions is too ubiquitous to be of analytical value. The proportion of such ions may be considerable, and will depend on the analyte, the ionization process used, and other compounds present in the sample. The time available for scanning is limited; specifically only a restricted number of scans may be acquired during the elution of a chromatographic peak. This is especially true of modern chromatographic techniques, such as capillary GC (including 'fast GC') and capillary electrophoresis (CE), in which the chromatographic peakwidth may be less than a second. Using SIM, only a restricted number of ions are monitored; generally, those that are diagnostic for a particular compound or class of compounds. In this way, the proportion of time spent monitoring each of these ions may be substantially increased, leading to an improvement in sensitivity toward the compound

**Figure 1** Changes in fragment ion intensities during the elution of  $d_0$ - and  $d_7$ -trimethylsilyl glucose from a packed column. (Reproduced from Sweeley *et al.*, 1966. *Analytical Chemistry*, copyright (1966) American Chemical Society.)

or compounds of interest. Estimates of this increase vary between 10- and 1000-fold depending on the analyte, matrix, ionization technique, and mass analyzer used. This enhancement in sensitivity, however, is necessarily achieved at the expense of unambiguous identification, since the entire mass spectrum is not recorded. If the ions to be monitored are selected prudently, however, the sensitivity gain may be significant without a concomitant diminution in the amount of analytically significant information derived. Comparisons of acquired data obtained using full data collection with authenticated spectra are typically based on the intensities of a limited number (normally eight) of the most significant ions in the mass spectrum. Library matching is normally based on the degree of agreement between the ratios of the ion intensities measured in the acquired spectrum and those in the library spectrum. If, therefore, the same ions are monitored in SIM mode, the same comparisons can be made with little reduction in analytically useful information. Indeed, the comparisons may be thought to be more reliable due to the improvement in signal-to-noise (S/N) ratio achieved by use of the SIM technique.

In general, the fewer ion peaks monitored, the greater the improvement in sensitivity. Taking the SIM technique to its extreme, sometimes only one ion is monitored; this is known as single ion monitoring (also abbreviated to SIM).

Most quantitative MS of organic compounds is conducted using a chromatographic inlet system and SIM. Compounds are separated from the matrix by the chromatographic system and enter the source of

the mass spectrometer after a characteristic retention time. The intensity of each characteristic ion may thus be monitored by SIM a number of times as the compound elutes. The use of SIM for quantification is more reliable than using full data collection because more time is spent monitoring the significant ions present in a chromatographic peak.

## Quantitative Mass Spectrometry with SIM

Quantification is effected by comparing the integrated peak areas or heights for the ions of interest with the responses obtained from a known aliquot of a standard compound. Either external or internal standards may be used. The response recorded for an external standard would be monitored in a preceding or subsequent analysis. Repeated measurements of the response for a known aliquot of an external standard may additionally be collated in order to monitor and correct for fluctuations in instrument response between analyses. More commonly internal standards are added at the beginning of the sample work up, and prior to any derivatization or wet-chemical process. Suitable compounds for use as internal standards include homologs or structurally related compounds possessing characteristic fragment ions, and which display similar chromatographic properties. These are distinguished from the analyte either by chromatographic separation or by differences in their mass spectra. For quantitative studies, the characteristic ion or ions

from the internal standards are monitored in a rapid sequence with those ions corresponding to the analytes. Modern instrumentation allows a number of SIM experiments to be performed at different time periods during the elution of a chromatogram, increasing the number of compounds that may be detected. Certain instrumentation also allows the simultaneous acquisition of full scan and SIM data.

A typical SIM experiment will monitor at least two ions (or ion transitions), resulting in the noncontinuous sampling of the chromatographic eluent. The quantified peak height obtained by SIM can be regarded as an estimate of the true height of a Gaussian curve based on a limited number of observations across the peak. To ensure that the error associated with this estimate is  $<1\%$ , at least 10 observations are required across the width of the peak, at half the observed height. Using SIM to monitor a pair of ions, at a typical scan speed of 20 ms per ion, 25 observations are generated each second facilitating quantification with a high degree of precision. In theory, error can also be reduced by using peak areas rather than heights for quantification. In practice, especially for small peaks, the errors introduced in attempting to delineate the baseline from a typical multicomponent chromatographic profile are usually much greater than those introduced in attempting to estimate a baseline level from which to measure the peak height.

Similar chemical behavior is a desirable attribute for an internal standard and, hence, isotopically labeled analogs of an analyte are frequently used as internal standards since they exhibit similar chemical and chromatographic behavior to the analyte. Deuterium-,  $^{13}\text{C}$ -, and  $^{15}\text{N}$ -labeled compounds are widely used as internal standards, the fragment ions monitored occurring at different mass-to-charge ratios (assuming that the charge-retaining fragments are isotopically labeled to some degree). The natural abundance of stable heavy isotopes present in the analyte make it desirable that the internal standard is at least three Daltons greater in mass than the analyte. When isotopically labeled analogs are employed, the relative response of the analyte with respect to its isotopically labeled counterpart is generally close to unity, since losses during sample preparation can be assumed to be similar for the two compounds.

The greatest accuracy attainable by MS is achieved by Isotope Dilution Mass Spectrometry using an 'exact signal matching' method. Like other SIM techniques, an isotopically labeled internal standard is added gravimetrically to the analyte, prior to extraction from its matrix. The quantity of internal standard is then adjusted, over a number of iterations, such that the signal obtained exactly matches that of

the analyte. This process is repeated with the internal standard and an authenticated sample of analyte (one of known purity and isotopic composition). Although time consuming, the instrumental variations, associated with all aspects of the method, are identical for both the analyte and standard, and this approach allows the quantitative determination of an analyte with a total uncertainty as low as 0.1–0.2%.

## Instrumentation and Techniques

The SIM technique is most commonly applied using quadrupole or magnetic sector instruments because of their ability to rapidly monitor different mass-to-charge ratios, even over significant mass ranges. Magnetic sector instruments achieve this by switching the accelerating voltage of the ion source and are limited in the range of masses that may be recorded. These instruments are, however, inherently more sensitive than quadrupole devices (typically a factor of 10) since the latter act as mass filters and incur transmission losses. In principle, other mass analyzers, including time-of-flight, ion trap, and Fourier-transform mass spectrometers can be adapted to acquire SIM data. In essence, these instruments take a 'sample' of the ions instantaneously present in the source for subsequent mass analysis and are potentially more sensitive than scanned instruments. Due to the fundamental nature of operation, however, little advantage is accrued by operating these instruments in the SIM mode.

### Sample Introduction Techniques

Most applications of SIM involve the coupling of the mass spectrometer to a means of chromatographic separation. This leads to a reduction in matrix effects and introduces an additional means of discriminating between compounds, namely the chromatographic retention time. Techniques such as GC, liquid chromatography (LC), CE, supercritical fluid chromatography, and thin-layer chromatography are all used in conjunction with mass spectrometers to form 'hyphenated' instruments such as GC-MS and LC-MS. The use of a chromatographic stage helps to resolve the compounds of interest from those that interfere with their determination, leading to a diminution in background chemical noise. Chromatographic conditions such as temperature gradient, column length, and choice of stationary and mobile phases are normally selected for optimum resolution and analysis time. The resolution of compounds in time also allows the possibility of monitoring different selected ions representative of various target compounds in different regions of the chromatogram.

The results from a chromatographic analysis by means of SIM are usually presented in the form of 'mass chromatogram', i.e., a plot of the intensity of a particular ion as a function of analysis time (Figure 2). Often this is plotted in conjunction with the total ion current (TIC), the sum of the intensities of all ions monitored over the same time period. The TIC is analogous to a chromatogram obtained from a 'universal' GC detector system, such as a flame ionization detector. Mass chromatograms may also be derived from full scan data. Whilst this technique is commonly employed for both the identification and quantitation of specific compounds, this process does not yield the improvement in sensitivity afforded by SIM.

The use of a chromatographic inlet technique leads to an additional means of characterizing and identifying a particular compound in a complex mixture, and hence to improved specificity. For a compound to be confidently identified by GC-MS-SIM, all the mass chromatograms representative of a particular

compound should maximize at the retention time corresponding to that compound, with the expected intensity ratios. Whilst it is commonplace to employ a chromatographic inlet system in conjunction with SIM, other methods are sometimes used. The elimination of a chromatographic stage can save considerable effort in sample preparation and derivatization, leading to a reduction in total analysis time, and can form the basis of rapid screening methods often known as 'fast and dirty methods'. Both flow injection MS and membrane inlet MS are frequently employed with SIM to monitor chemical processes and reactions in real time.

### Derivative Formation

In cases where compounds are too polar or thermally unstable to be amenable to GC analysis, the situation may be improved by the formation of a suitable derivative with characteristics that render it more amenable to chromatographic analysis. In addition, derivative formation can enhance sensitivity and selectivity by altering the fragmentation mechanism of the molecule. A further beneficial effect of derivatization is that it normally results in a compound possessing characteristic ions at mass-to-charge ratios different from those of the original compound. Selection of an appropriate derivative can, therefore, lead to the choice of ions for monitoring by SIM in a region of the mass spectrum (usually at higher mass), which is less prone to chemical noise, and consequently to a further improvement in S/N ratio.

Derivatization may, in certain cases, be effected within the injection port of a GC-MS system. An ion pair/supercritical fluid extraction and injection port derivatization process has been presented as a method for the quantitative determination of aromatic and aliphatic sulfonated surfactants in sewage sludge by GC-MS with SIM (Figure 2).

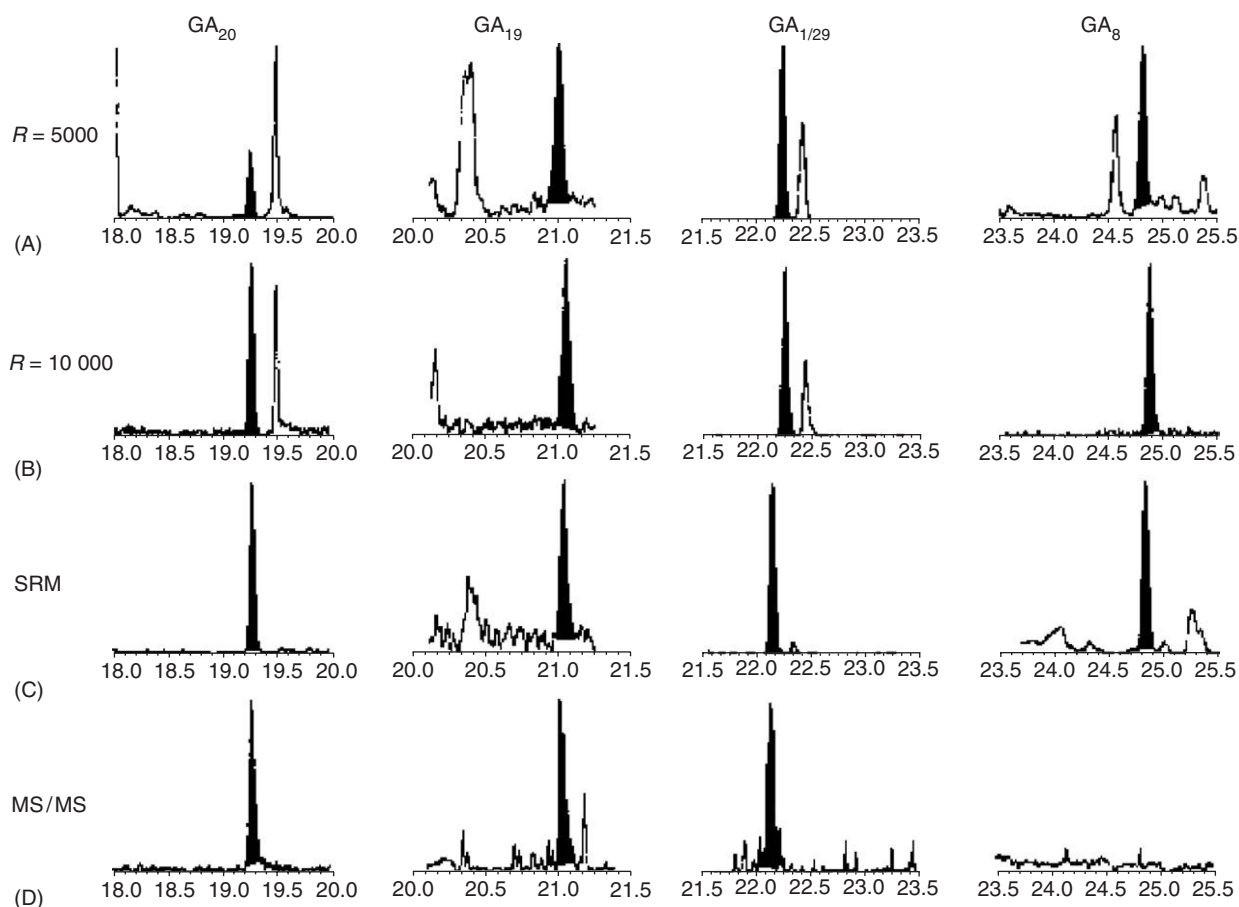

Careful selection of the derivatization technique may also be employed to enhance the detection limit of an analyte. The conversion of amphetamines to tetrafluorophthaloyl derivatives yields compounds possessing high electron capture cross-sections and the sensitivity toward such compounds, using negative ion chemical ionization (NICI) can be better than that achieved using positive ion formation by two orders of magnitude. Employing NICI in conjunction with SIM, the detection of amphetamine derivatives in quantities as small as 10 fg (30 amol) may be effected.

### High-Resolution Selected Ion Monitoring

An improvement in the specificity of the SIM technique may be achieved by the use of high-resolution

**Figure 2** Selected ion chromatograms for homologues of secondary alkanesulfonate surfactants (SAS) using  $[M - 138]^+$  ions at  $m/z$  196, 210, 224, and 238, and of linear alkylbenzenesulfonate surfactants (LAS) using  $[M - 55]^+$  ions at  $m/z$  299, 313, 327, and 341 in an unfractionated ion pair/SFE extract of sewage sludge. **Figure 3** SIM detection of gibberellins using: (A) 5000 resolution; (B) 10 000 resolution; (C) SRM using a sector instrument; and (D) SRM using a four-sector instrument. (Reproduced with permission from *Analytical Chemistry* 76: 1711–1716. Copyright (1995) the American Chemical Society.)

MS. When using an MS with unit resolution, the intensity recorded for a selected ion may be affected by contributions from the isotopomers of neighboring ions or nominally isobaric species. Any response measured may also contain a contribution from an adjacent mass peak rather than the intended peak. Increasing the resolution of the mass spectrometer reduces the number of background ions recorded, hence improving the detection limit. Typically, high resolution (usually 5000–10 000) SIM affords an increase in S/N of 2–10-fold. The certainty with which a compound can be identified by SIM is also greatly improved by high resolution, since the ions measured may correspond to only a single elemental composition. High-resolution sector instruments are now routinely employed in applications requiring the ultimate sensitivity and confidence attainable, often for analytes in extremely complex matrices. Typical applications include the determination of pesticides, polychlorinated biphenyls, and dioxins in environmental materials and the determination of controlled substances such as anabolic steroids in human and

animal sports. **Figure 3** illustrates the effect of increased mass resolution for the determination of endogenous growth regulators (gibberellins) in crude extracts of plant material analyzed by GC–MS SIM. Increasing the resolution from 5000 to 10 000 reduces the background ion current leading to an improvement in S/N ratio and hence detection limit.

### Selected Reaction Monitoring

An alternative means of enhancing both the specificity and detection limits attainable by SIM is afforded by use of tandem mass spectrometry (MS/MS). The MS/MS equivalent of SIM is termed selected reaction monitoring (SRM), sometimes incorrectly referred to as multiple reaction monitoring. In this technique, selected precursor-product gas phase ion reactions, specific to the analyte and an internal standard, are recorded in rapid succession.

Although many designs of MS/MS instruments exist, SRM is typically performed with sector instruments (in linked scan mode), triple quadrupoles, or

hybrid instruments, including four sector instruments. Like conventional SIM operation, each type of instrument offers certain advantages and limitations. Triple quadrupole instruments are the most widely adopted because of their ability to record ion transitions in a very rapid sequence. Hybrid instruments, incorporating high-resolution capability, offer the advantage of high-specificity precursor ion selection. SRM offers significant reduction in instrument noise (and hence increase in S/N ratio) even when compared to high-resolution SIM (Figure 3). In this example, SRM provided greater sensitivity and selectivity than high-resolution SIM. Use of a four-sector mass spectrometer led to a further increase in specificity (since both precursor and product ions are transmitted at high resolution) but a reduction in sensitivity.

### **Ionization Methods with Selected Ion Monitoring**

Any ionization technique may be used in combination with SIM, monitoring either positive or negative ions. Electron ionization (EI) is the most commonly used ionization technique and employs energetic electrons that generally induce a high degree of fragmentation in the analyte. This typically generates a range of ions that may be monitored in SIM. The use of 'softer' ionization techniques, such as chemical ionization (CI), often leads to a higher proportion of the ion current being carried by the higher-mass ions, typically the protonated molecule. The monitoring of these species affords improved sensitivity and less interference from other components. Since molecular mass is one of the most characteristic features of a molecule, selectivity is also often enhanced. In particular, NICI has been extensively used with SIM in quantitative organic MS. The negatively charged molecular ion is often more stable than its cationic radical counterpart, and may fragment by a different pathway, yielding supplementary information to that derived from the positive EI or CI mass spectrum. Negative ions formed by either electron capture or ion-molecule reactions in the ion source may be monitored. Nucleophilic addition reactions in the source with anions of low proton affinity, such as  $\text{Cl}^-$ , may lead to the formation of stable adducts. These  $[\text{M} + \text{Cl}]^-$  complexes have been used, for example, to search for the presence of traces of certain explosives in security surveillance applications. The formation of chloride addition complexes, in an atmospheric pressure chemical ionization (APCI) source, leads both to improved detection limits for the explosives in question and to enhanced selectivity, since two adduct ions may be monitored for each explosive, corresponding to complexes formed with the  $^{35}\text{Cl}$  and  $^{37}\text{Cl}$  isotopes. The observation of ions at

masses corresponding to adducts of both isotopes, in the expected relative abundance, gives a far more reliable indication of the presence or absence of an analyte than monitoring a single ion.

Most LC-MS sample introduction techniques, such as thermospray, electrospray, and APCI, do not employ an electron beam to induce ionization, and lead to the formation of predominantly molecular ion species. This leads to the formation of higher mass fragments that may be monitored by SIM or SRM. Such techniques are frequently used in biomedical applications, and find particular application in the quantitative analysis of labile or polar compounds such as biomolecules from complex biological matrices.

In some circumstances, a depletion in the amounts of a particular CI reagent ion has been monitored by SIM as compounds elute from a chromatographic inlet. Although this is neither a particularly sensitive nor selective technique, semiquantitative data may be obtained without calibration for a number of compounds. This technique has been referred to as 'reagent ion monitoring'. A development of this technique is the selected ion flow tube-mass spectrometer, which employs a quadrupole mass spectrometer to introduce selected reactant ions into a reaction flow tube. Volatile organic compounds (VOCs) introduced into this region react with the selected reagent ions and the products are mass analyzed by a subsequent quadrupole mass analyzer. This technique has already found wide application in the quantitative analysis of parts per billion amounts of VOCs present in breath gases or evolved from environmental samples.

### **Applications**

The SIM technique finds use primarily in quantitative studies of trace analytes in complex mixtures. The technique has been utilized in a diverse range of applications including forensic science, toxicology, environmental monitoring, biochemistry, clinical chemistry, and geochemistry. In applications such as these, the analyte is often present in a complex matrix comprising a great number of compounds that may mask its presence or otherwise inhibit its detection.

The presence or absence of specific trace components in such complex matrices is often difficult to establish due to interference from a high abundance of compounds that co-elute from the chromatographic system used. This makes the acquisition of 'clean' mass spectra difficult. Some compounds may simply be present in insufficient quantities to allow a high-quality spectrum to be obtained. Hence, it is

desirable to increase the sensitivity of the mass spectrometer toward the analytes sought. SIM data may in such cases provide a qualitative solution to the question of the presence or absence of a particular analyte. It is not usually possible simply to increase the amount of analyte entering the source of the mass spectrometer by injecting a more concentrated solution of the extract into the GC-MS. In mass spectrometric techniques employing a chromatographic

inlet, the quantity of a particular component, which may be introduced into the source, is limited by its concentration relative to the most abundant component present. In the search for trace components, therefore, the chromatographic stage can be the limiting factor. Minor components may thus become masked by other substances in the mixture, and in adverse cases may not be discerned from the background noise. The SIM technique is commonly used

**Figure 4** SIM detection of sanfetrinem in plasma: (A) a blank sample compared to spiked plasma; (B) a representative chromatography of a real patient sample. (Reprinted with permission from Nardi *et al.*, 2001. *Journal of Chromatography B* 767: 193–201; © from Elsevier.)

to establish the presence of trace components in such mixtures. SIM and SRM are recognized as the most commonly used biomedical mass spectrometric techniques, specifically in the fields of drug development and screening. **Figure 4** shows a typical application of LC–MS/MS SIM to the determination of sanfetrinem, a broad spectrum antibacterial agent, in human plasma. Because of the high specificity of the technique, minimal sample preparation and chromatography are required. The sample is simply deproteinized with acetonitrile, diluted with water, and injected onto a short chromatography column (5 cm – C<sub>18</sub>), the analyte eluting in less than 2 min. The extreme simplicity of the chromatogram obtained reflects the high selectivity of the technique, even when the analyte is present in a highly complex biological matrix. Using this simple and rapid technique, this antibiotic could be quantified in the range 10 ng–5 µg ml<sup>−1</sup> in human plasma.

## Introduction

Multidimensional mass spectrometry (MS) involves the use of two or more mass analysis procedures one after the other in order to facilitate the selective fragmentation of specific ions in a complex mixture. Many different types and configurations of instruments can be used, some of which separate the consecutive mass analysis events spatially, while others carry out two or more analyses in the same compartment but separate them temporally. Tandem mass spectrometry (MS/MS or MS<sup>2</sup>) often involves two physically distinct mass analyzers separated by a collision cell to induce the fragmentation of precursor (primary or parent) ions. Higher-order analysis (MS<sup>3</sup> and above) involves multiple rounds of collision and ion extraction, and is usually carried out in ion trap or ion cyclotron resonance instruments, which have ion storage and selection capability. Multidimensional MS is particularly useful where the analyte is very complex, where ionization produces relatively few structurally diagnostic ions, or where useful ions are obscured or suppressed by others

introduced either in the analyte itself or in the sample matrix. Depending on the scan mode, MS/MS can be used to characterize individual ions, or to search for specific ion fragments that are diagnostic for certain classes of chemical compounds. This article discusses the instrumentation and scan modes used in multidimensional MS and briefly outlines some of its major applications.

## Instrumentation

There are two major groups of instruments used in tandem and multidimensional MS. The first group encompasses those instruments in which two or more mass analyzers are assembled in series, such that parent or precursor ions emerging from the ion source are selected in the first analyzer, fragmented in a collision cell, and the product (secondary or daughter) ions are then characterized in the second and subsequent analyzers. The second group encompasses instruments capable of ion storage, such that precursor ions are retained, fragmented, and the product ions analyzed in the same chamber. Selected product ions can then be retained and fragmented, and the second-generation product ions can be analyzed. This procedure can be repeated as many times as

to establish the presence of trace components in such mixtures. SIM and SRM are recognized as the most commonly used biomedical mass spectrometric techniques, specifically in the fields of drug development and screening. **Figure 4** shows a typical application of LC–MS/MS SIM to the determination of sanfetrinem, a broad spectrum antibacterial agent, in human plasma. Because of the high specificity of the technique, minimal sample preparation and chromatography are required. The sample is simply deproteinized with acetonitrile, diluted with water, and injected onto a short chromatography column (5 cm – C<sub>18</sub>), the analyte eluting in less than 2 min. The extreme simplicity of the chromatogram obtained reflects the high selectivity of the technique, even when the analyte is present in a highly complex biological matrix. Using this simple and rapid technique, this antibiotic could be quantified in the range 10 ng–5 µg ml<sup>−1</sup> in human plasma.

## Introduction

Multidimensional mass spectrometry (MS) involves the use of two or more mass analysis procedures one after the other in order to facilitate the selective fragmentation of specific ions in a complex mixture. Many different types and configurations of instruments can be used, some of which separate the consecutive mass analysis events spatially, while others carry out two or more analyses in the same compartment but separate them temporally. Tandem mass spectrometry (MS/MS or MS<sup>2</sup>) often involves two physically distinct mass analyzers separated by a collision cell to induce the fragmentation of precursor (primary or parent) ions. Higher-order analysis (MS<sup>3</sup> and above) involves multiple rounds of collision and ion extraction, and is usually carried out in ion trap or ion cyclotron resonance instruments, which have ion storage and selection capability. Multidimensional MS is particularly useful where the analyte is very complex, where ionization produces relatively few structurally diagnostic ions, or where useful ions are obscured or suppressed by others

introduced either in the analyte itself or in the sample matrix. Depending on the scan mode, MS/MS can be used to characterize individual ions, or to search for specific ion fragments that are diagnostic for certain classes of chemical compounds. This article discusses the instrumentation and scan modes used in multidimensional MS and briefly outlines some of its major applications.

## Instrumentation

There are two major groups of instruments used in tandem and multidimensional MS. The first group encompasses those instruments in which two or more mass analyzers are assembled in series, such that parent or precursor ions emerging from the ion source are selected in the first analyzer, fragmented in a collision cell, and the product (secondary or daughter) ions are then characterized in the second and subsequent analyzers. The second group encompasses instruments capable of ion storage, such that precursor ions are retained, fragmented, and the product ions analyzed in the same chamber. Selected product ions can then be retained and fragmented, and the second-generation product ions can be analyzed. This procedure can be repeated as many times as

necessary to gain useful structural information from subsequent generations of product ions.

### Multisector Instruments

The first type of instruments developed for MS/MS were double-sector mass spectrometers consisting of magnetic (B) and electrostatic (E) sectors arranged in series. The two sectors can be arranged in either configuration, i.e., BE or EB, although the BE configuration (reversed geometry) has become the most widespread. The principle of MS/MS analysis in such instruments is that precursor ions fragmenting in the field-free region downstream of the magnetic sector will yield product ions with approximately the same velocity as the precursor. Since the electrostatic analyzer separates ions according to their kinetic energies, and kinetic energy is a product of mass and velocity, product ions with identical velocities will be separated according to mass. As well as double-sector instruments, a number of manufacturers produce multisector instruments with three, four, or five magnetic and electrostatic analyzers in series. Two double-focusing instruments have been combined to generate a four-sector instrument with the configuration BEEB, incorporating multiple collision cells to facilitate both high- and low-energy collisions (Figure 1). The Autospect-T, produced by Micromass Inc., is an example of a commercially produced mass spectrometer which has five sectors in the configuration EBEBE.

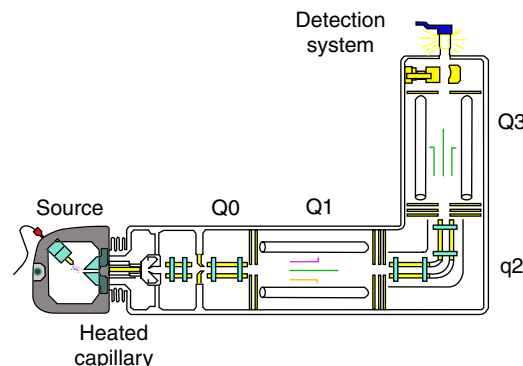

### Triple Quadrupole Instruments

The most straightforward way to carry out MS/MS analysis is to arrange two mass analyzers in tandem, placing an ion source at one end, a detector at the other, and a collision cell in the middle. The most widely used MS/MS instrument in this category is the triple quadrupole, in which three quadrupole analyzers are arranged in series (Figure 2). The first and

third quadrupoles are used as analyzers, and may either scan the ion stream or select ions of a fixed  $m/z$  ratio, while the second quadrupole is run in radio frequency (rf) mode and operates as the collision cell. The conventional representation for this geometry is QqQ, where Q represents a quadrupole operating as a mass filter and q represents a quadrupole operating in rf mode and letting ions of any  $m/z$  value through. The second quadrupole also focuses the ion stream, preventing the loss of ions scattered during collision. The number of collisions occurring in a triple-quadrupole mass spectrometer is generally much larger than that observed in a sector instrument, resulting in a more efficient conversion of precursor ions into product ions. Other advantages of the triple quadrupole include economy, ease of use, and convenient switching between different operational modes. However, the instruments have a restricted mass range, low sensitivity, and a limited resolution.

### Hybrid Instruments

Hybrid instruments combining magnetic sector and quadrupole analyzers have been developed, which

**Figure 2** Design of a triple-quadrupole mass spectrometer, where q2 operates as the collision cell.

**Figure 1** Design of a four-sector MS/MS instrument with the configuration BEEB. FFR = field-free region.

are simpler to operate than the multisector instruments described above. The configuration BEqQ, which uses the magnetic and electrostatic sectors to separate the precursor ions and a quadrupole collision chamber and mass analyzer to generate and separate the product ions, is shown in Figure 3. This instrument allows high-resolution selection of parent ions, facilitates both high- and low-energy collisions, and achieves unit resolution of product ions. Other configurations, such as EBqQ, have also been used.

Both quadrupole and sector analyzers have also been combined with time-of-flight (TOF) analyzers, to give BE-TOF and QqTOF configurations. In the

former case, the BE analyzer is joined to an orthogonal TOF analyzer, such that product ions with the same velocity as the precursor ion are accelerated orthogonally into a field-free tube, thus traveling at a velocity proportional to their  $m/z$  ratio. The hybrid QqTOF instrument operates on similar principles, and is renowned for its high resolution and sensitivity across the full mass range (Figure 4). Such instruments can be more than 100 times more sensitive than triple quadrupoles for MS/MS experiments and have an  $m/z$  upper limit in excess of 20 000 mass units. One disadvantage is that only low-energy collisions are possible, resulting in incomplete fragmentation.

**Figure 3** Design of a hybrid sector-quadrupole instrument with the configuration BEqQ. FFR = field-free region.

**Figure 4** Design of a hybrid Q-TOF instrument.

### TOF-TOF (Tandem TOF)

To overcome the limitations of QqTOF and other instruments, mass spectrometers have been designed with two orthogonally arranged TOF analyzers separated by a collision cell. The high-energy collisions that are possible in such instruments are particularly useful in proteomics applications, where full fragmentation can reveal differences between the amino acids leucine and isoleucine, which have identical molecular masses. In order to focus all the product ions without changing the reflectron voltage, conventional TOF/TOF instruments initially used a low-power source to generate the primary ions, and then re-accelerated the product ions after fragmentation, using either a second source or by lifting the voltage of the collision cell (Figure 5). Contemporary instruments have two curved reflection analyzers separated by a collision cell, which accommodates the full range of product kinetic energies. Collision energies can be as high as 20 keV for an instrument with a 20 kV ion acceleration voltage, therefore facilitating complete fragmentation of the precursor ions.

### Ion-Storage Devices

Two types of ion storage instrument have been used for MS<sup>n</sup> applications: the quadrupole ion-trap (QIT) (Figure 6) and the Fourier transform ion cyclotron resonance (FT-ICR) analyzer (Figure 7). The ion trap consists of a chamber surrounded by a ring electrode and two end-cap electrodes. The voltage applied to the ring electrode determines which ions remain in the trap. Ions above the threshold  $m/z$  ratio remain in the trap while others are ejected through small holes in the distal end-cap electrode. A mass spectrum of intact ions can be obtained by gradually increasing the voltage in the ring electrode so that ions of progressively increasing  $m/z$  ratios are ejected over time. For MS<sup>n</sup> analysis, the trapped precursor ions can be fragmented by injecting a stream of helium gas, and the resulting product ions can be ejected by ramping the voltage of the ring electrode to generate a spectrum. Multiple rounds of analysis can be carried out because one of the fragment ions from the first experiment can be retained in the trap and subjected to further collisions.

**Figure 5** Design and layout of the tandem time-of-flight mass spectrometer, coupled to a MALDI source.

**Figure 6** Design and layout of the quadrupole-ion trap mass spectrometer, coupled to an ESI source.

**Figure 7** Design principles of the Fourier transform ion cyclotron resonance mass spectrometer.

The FT-ICR analyzer is the most complex and difficult to operate, but has by far the highest resolution, mass accuracy, and sensitivity. The operating principle is that ions in a magnetic field will orbit at a frequency that is related to the ion's mass ( $m$ ), charge ( $z$ ), and the strength of the magnetic field ( $B$ ). This is called the cyclotron frequency ( $f_c$ ). The relationship can be described by the following equation:

$$m/z = B/2\pi f_c$$

Therefore, all ions with the same  $m/z$  value will orbit with the same cyclotron frequency in a uniform magnetic field, and this collection of ions is known as an ion packet.

Orbiting ions of a particular  $m/z$  value are then excited using an applied rf field, which causes the cyclotron radius to expand. If the frequency of the applied field is the same as the cyclotron frequency of the ions, the ions absorb energy thus increasing their velocity (and the orbital radius) but keeping a constant cyclotron frequency. As the selected ions cycle between the two electrodes, electrons are attracted first to one plate and then the other, with the same frequency as the cycling ions (i.e., in resonance with the cyclotron frequency). This movement of electrons is detected as an image current on a detector. The image current is then converted, by Fourier transformation, into a series of component frequencies and amplitudes of the individual ions. Finally, the cyclotron frequency values are converted into  $m/z$  values to produce the mass spectrum. Various forms of collisional activation can be used to fragment the precursor ions in an FT-ICR instrument (see below) but in simple terms the principle of  $MS^n$  analysis is the same as described above for the ion-trap analyzer. Selected precursor ions are fragmented and gradually increasing frequencies are used to induce resonance in product ions of progressively increasing  $m/z$  ratios,

producing current images that are transformed into mass spectra. At each stage of the analysis, product ions can be retained and subjected to further rounds of fragmentation and excitation. The major difference between ion traps and FT-ICR instruments is that the latter are nondestructive. Ions are not expelled to a detector during analysis, but are cycled within the device.

### The Collision Cell

Fragmentation occurs spontaneously in many ionization sources, but the product ions generated in this way are neither diverse nor abundant enough to allow the complete characterization of the precursor ion. Fragmentation can also be induced, e.g., by in-source collision in electrospray sources or by post-source decay in matrix-assisted laser desorption/ionization (MALDI) sources, but fragmentation prior to the separation of precursor ions can make the analysis of complex analytes very difficult. The fragmentation of selected precursor ions is achieved by placing a collision cell between the first and second mass analyzers in a tandem mass spectrometer. Collision occurs when the ion stream passes through a jet of inert gas, such as argon or xenon. The fragmentation of precursor ions by collision with neutrals in this manner is called collision-induced dissociation (CID). (The term collision-activated dissociation is also used.) In  $MS/MS$  instruments with tandem analyzers, the collision cell is a discrete chamber between the two analyzers. It may be a simple chamber filled with gas, in which case the ions are scattered as well as fragmented, but more usually the collision cell is contained within a quadrupole running in rf mode, which allows the ion stream to be focused. In  $MS^n$  instruments such as the ion trap and the ICR analyzers, there is no separate collision

cell. Instead, gas is introduced into the ion-trap chamber using an operator-controlled valve.

In an FT-ICR instrument, fragmentation may be achieved by colliding ions with neutrals (CID) but various other strategies are available, such as collision with surfaces (surface-induced dissociation) or bombardment with ultraviolet or infrared radiation from a laser (ultraviolet photodissociation and multiphoton infrared photodissociation). Dissociation may also be achieved by the absorption of blackbody radiation produced by a heated vacuum chamber walls (blackbody infrared dissociation). An advantage of these radiation-induced fragmentation methods is that gas pulses are no longer required. Sustained off-resonance irradiation is the preferred, radiation-based method for FT-ICR MS<sup>n</sup> because it is the simplest to implement and tune. Very low energy and multiple excitation collisional activation techniques are also available.

## MS/MS and MS<sup>n</sup> Scan Modes

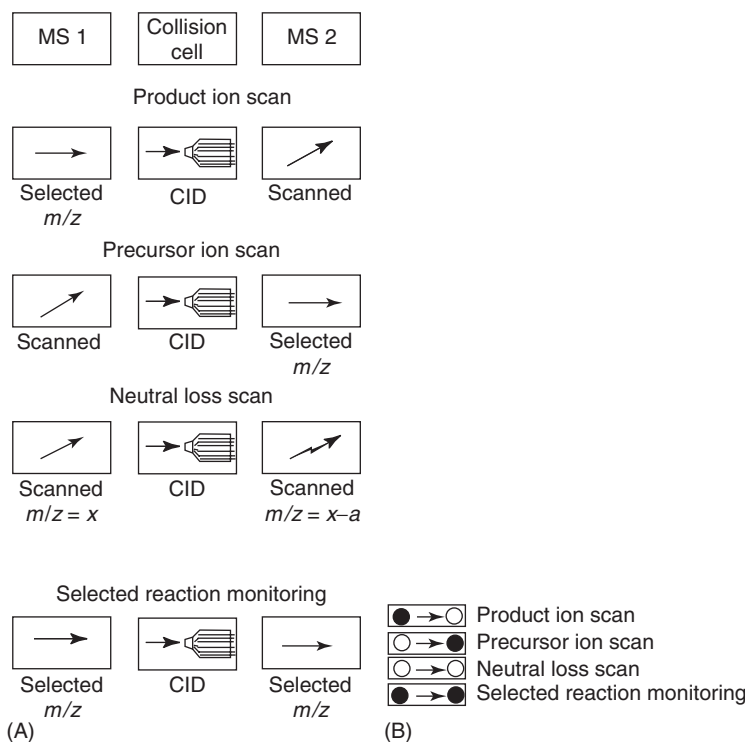

Four scan modes are available in MS/MS analysis. The three that are used most frequently are product ion scanning, precursor ion scanning, and neutral loss scanning, all of which generate mass spectra across a given mass range. The remaining mode is used for selected reaction monitoring and results in

the production of a single type of fragment ion. All of these scan modes are possible in tandem instruments but only product ion scanning is possible in trapping instruments. Kondrat and colleagues proposed a simple symbolic nomenclature to represent these scan modes, in which a filled circle represents mass analysis at a fixed  $m/z$  ratio and an open circle refers to a mass analyzer scanning the ion stream. The nomenclature is shown in Figure 8.

### Product Ion Scan Mode (MS/MS)

In this mode, also known as daughter ion scanning, the mode scheme is select–dissociate–scan ( $\bullet \rightarrow \circ$  in Kondrat symbols). For sequential instruments where mass analysis events are separated in space, the first analyzer is fixed to select intact precursor ions of a particular  $m/z$  ratio from the source, these are directed into the collision cell, which fragments the chosen ion and focuses the products into the second analyzer. The second analyzer scans the incoming stream of product ions over an appropriate mass range and produces a mass spectrum. Product ion scanning is one of the most widely used scan modes in QqQ, Q-TOF, and tandem TOF instruments.

In sector instruments with reversed geometry, product ion scanning as depicted above is known as MILES (mass-analyzed ion kinetic energy spectrometry). The magnet is used to select the precursor

**Figure 8** (A) Schematic representation of the four scan modes used in tandem mass spectrometry. (B) Kondrat symbolism, where a filled circle indicates a fixed mass analyzer and an open circle indicates a scanning analyzer.

ion, which is fragmented in the field-free region between the magnetic and electrostatic sectors, and the product ions are then separated according to their kinetic energies by the electrostatic analyzer. However, because the precursor and product ions have the same velocity, scanning both sectors at the same time while maintaining a constant ratio between  $B$  (the magnetic field strength) and  $E$  (the electrostatic field strength) allows precursor ions and derivative product ions to be detected at the same time, even if fragmentation occurs between the source and the first detector. This is one example of a linked scan, where both analyzers are scanned simultaneously to preserve a predetermined relationship between their fields.

In ion-trap and FT-ICR instruments, product ion scanning is achieved by the ‘tandem-in-time’ route. Ions entering the trap at time 1 are subjected to a static field that selects for ions of one particular  $m/z$  ratio. These ions are collided with a stream of neutral atoms, a surface, or with radiation (see above) at time 2, which activates them and causes fragmentation. The resulting product ions are then scanned with a steadily increasing rf, which (in the case of a QIT instrument) accelerates them toward a sequential  $m/z$  hit detector.

### Product Ion Scan Mode ( $MS^n$ )

$MS^n$  analysis in ion traps and FT-ICR instruments is achieved by extending the ‘tandem-in-time’ principle, and iterating the time sequence discussed above. Product ions generated in the first round of fragmentation are scanned to give the product ion mass spectrum, but individual product ions can then be selected as second-round precursors, and fragmented again. Similar experiments up to  $MS^5$  have been carried out using sequentially aligned quadrupole analyzers (penta-quadrupole) but this is cumbersome and rarely used. In contrast,  $MS^n$  analysis in ion traps and FT-ICR is routinely carried out to  $MS^{10}$  and above, with at least one report describing the  $MS^{12}$  analysis of a complex glycoprotein sample.

### Precursor Ion Scan Mode

The precursor ion scan mode scheme is scan–dissociate–select ( $\circ \rightarrow \bullet$  in Kondrat symbols, and the opposite of the product ion scan mode). This mode is used in instruments containing two or more analyzers in series, but is unavailable in ion storage devices. The first analyzer scans the ion stream over a particular mass range and ions of increasing  $m/z$  value are passed to the collision cell and fragmented. The second analyzer is fixed to select product ions of a specific  $m/z$  ratio. Therefore, ions passing through

the first analyzer will be detected only if they yield the appropriate product ions during fragmentation. This mode is often used where the aim is to identify compounds in the analyte that carry a particular functional group. For example, organic compounds containing a phenyl group can be detected if the second analyzer is set to detect positive ions with an  $m/z$  value of 77, which corresponds to  $[C_6H_5^+]$ . Similarly, when MS/MS is used to analyze proteins or peptides in negative ion mode, the second analyzer can be set to detect ions with an  $m/z$  value of 79, which corresponds to  $[PO_3^-]$  and thus identifies proteins containing a phosphate group. False positives can occur in precursor ion scan mode if ions with the same  $m/z$  value as the selected group-specific fragment are generated by other fragmentation events. Precursor ion scans can also be performed using sector instruments if the magnetic and electrostatic sectors are linked in the appropriate fashion.

### Neutral Loss Scan Mode

The scheme for neutral loss scan mode is scan–dissociate–scan ( $\circ \rightarrow \circ$  in Kondrat symbols) and is an example of a linked scan using contemporary triple-quadrupole and hybrid instruments. Like the precursor ion scan, this mode is not available in trapping instruments but can be achieved in sector instruments by adjusting the relationship between the magnetic and electrostatic field strengths. In this mode, both the first and second analyzers are used to scan the ion stream, but the second analyzer is set out of register with the first so that it scans a parallel ion range at an  $m/z$  ratio that is lower by a fixed amount. This achieves the same aim as the precursor ion scan, i.e., it can help to identify compounds that carry specific functional groups, but does so in a different way – by scanning for the loss of those groups. In proteomics applications, for example, the second analyzer can be set to scan at 98 mass units below the first, which will specifically detect peptides that have lost a neutral  $H_3PO_4$  group. This helps to identify proteins that have phosphate groups attached to them.

### Selected Reaction Monitoring

The Kondrat representation for selected reaction monitoring is  $\bullet \rightarrow \bullet$ , i.e., select–dissociate–select. This mode can be used to monitor either single reactions (single reaction monitoring) or multiple reactions (multiple reaction monitoring) and is essentially a quantitative target analyte scan. In the case of a triple-quadrupole instrument, Q1 is set to select a particular  $m/z$  ratio, ions of this type are fragmented in the collision cell, and Q3 is set to detect specific products of that reaction, again by selecting a particular  $m/z$  ratio. For the detection of

particular compounds, selective reaction monitoring is  $\sim 10$  times more sensitive than neutral loss scanning, which in turn is  $\sim 10$  times more sensitive than product ion scanning.

## Applications of MS/MS and MS<sup>n</sup>

Tandem mass spectrometry has impacted on many areas of science, including organic chemistry, biochemistry, genetics, pharmacology, and medicine. In organic chemistry, the ability of MS/MS to fragment complex organic molecules and determine fragment ion masses helps not only to reveal molecular structures but also to distinguish between very similar organic molecules and perform quantitative analysis.

With a high-resolution mass spectrometer it is possible to achieve an accuracy of approximately one part in one million, which allows ions such as  $C_6H_{12}^+$  and  $C_4H_4O_2^+$  to be distinguished even though their molecular masses differ by only 0.0728 mass units. Although the fragmentation pattern of a given organic molecule cannot be predicted with accuracy, peaks can often be associated with particular chemical groups on an empirical basis. MS/MS can be applied to endpoint samples and reactions in progress, the latter providing important information about the structures of intermediates and by-products. When such studies are combined with isotopic labeling, the distribution of labeled atoms in the fragment ions can show which atoms are involved in particular reactions and whether intramolecular or intermolecular processes are involved. Specific applications in organic chemistry include the analysis of metabolic profiles, the detection of chemicals and explosives in the environment and in forensic samples, and the characterization of chemical libraries, as discussed below.

In recent years, MS/MS has played an important role in combinatorial chemistry, a discipline in which large libraries of molecules are created so that they can be screened as drugs. MS/MS is one of the most useful techniques for the analysis of structure–activity relationships in potentially therapeutic molecules, helping to determine which particular functional groups, revealed as product ions, are responsible for positive therapeutic effects. Although bioassays are needed to confirm the therapeutic properties of drugs, MS/MS can help to identify the most active components of libraries by correlating structural data with the results from functional assays. This can determine which features of each molecule are likely to be most important for interactions with drug targets. Soft ionization techniques such as electrospray ionization (ESI) and MALDI coupled to MS/MS have been at the forefront of new discovery

paradigms, including the identification and analysis of drug–target interactions, receptor–ligand binding, and enzyme–substrate–inhibitor relationships.

MS/MS has also become established in biochemistry and genetics, both as a discovery tool and a diagnostic technique. The high sensitivity of contemporary tandem and multidimensional mass spectrometers means they can be used to detect disease-specific molecules in tissue and blood samples down to the femtomole level. For example, MS/MS neutral loss scanning is used to detect increased levels of phenylalanine in the blood of newborn infants, to increase the detection rate and lower the false-positive rate associated with screening for phenylketonuria. Selected reaction monitoring is used widely to detect drug residues, such as steroids in athletes and domestic animals and in adulterated foods.

Perhaps the most important application of MS/MS in biology at the beginning of the new millennium is in the analysis of proteins, which until 1995 could only be sequenced using laborious methods based on cyclical chemical degradation. The advent of MALDI and ESI ion sources now permits the soft ionization of peptides, whose masses can be determined and correlated to those calculated from protein sequences stored in sequence databases. Unfortunately, the information provided by MS analysis is often insufficient for protein identification, which is where MS/MS comes into its own. Where peptide mass fingerprinting fails to identify any proteins matching those present in a given sample, the CID spectrum of one or more individual peptides may provide important additional information. The data can be used either in its uninterpreted form, to search for peptides whose sequences could yield fragments of identical mass to the experimentally determined peptide fragments, or the mass spectrum can be interpreted to give short peptide tags that can be used to search sequence databases for matching sequences. Taken to its extreme, this method can even be used for the *de novo* sequencing of proteins, since fragment ions can be assembled in order of increasing size, with differences between adjacent members of a nested set separated by masses that can be correlated with those of specific amino acids. As discussed above, precursor ion scanning and neutral loss scan modes can be used to identify proteins with particular forms of modification, such as phosphoproteins and glycoproteins. Multidimensional MS analysis has been especially useful for the sequencing and structural analysis of complex carbohydrates and glycoproteins.

## Stable Isotope Ratio

**K J Welham**, University of Hull, Hull, UK

© 2005, Elsevier Ltd. All Rights Reserved.

This article is a revision of the previous-edition article by I P Wright, pp. 2869–2877, © 1995, Elsevier Ltd.

## Introduction

The term ‘stable isotope ratio’ in its normal context is restricted to a small group of elements (i.e., hydrogen, carbon, nitrogen, oxygen, and sulfur) that are readily converted into simple gaseous compounds for the purpose of isotope ratio determination using a mass spectrometer. This article will focus on the instrumentation used to measure stable isotope ratios, from dual inlet systems operating with dynamic gas flow through later developments for interfacing to gas chromatography and on to newer static vacuum designs. The fields of application of stable isotope ratio mass spectrometry are broad, transcending the life sciences, atmospheric chemistry, oceanography, agriculture, archaeology, cosmochemistry, geological sciences, etc. In these examples, stable isotopes are used, among other things, to elucidate metabolism, the sources of materials, to constrain the extent of chemical reactions, monitor diffusion, assess formation temperatures, and so on.

## Dual Inlet Mass Spectrometry

Dual inlet mass spectrometers designed for the purpose of analyzing gas samples were first built in the 1940s. Despite improvements in hardware components such as power supplies, electronic detection systems, and computer control, the modern commercially available mass spectrometer resembles its

forebears in many respects. A schematic diagram of a typical dual inlet mass spectrometer is shown in **Figure 1**. There are two identical inlets, one containing a sample gas of unknown isotopic composition and one containing a reference gas.

Each inlet consists of a variable volume, a cold finger, and a capillary crimped near to its termination. Both inlets are connected to a changeover valve mounted in close proximity to the ion source of the mass spectrometer, which is pumped to a ‘background pressure’ of  $<10^{-10}$  Torr ( $\sim 10^{-8}$  Pa; 1 Torr  $\sim 133$  Pa).

Sample and reference gases, stored at relatively high pressures in each of the inlets, flow continuously through the capillaries and into the changeover valve. At the end of each capillary a crimp allows fine-scale adjustment of flow rate (a procedure carried out only once, when the instrument is first commissioned). The changeover valve selects one of the gases for entry to the mass spectrometer, resulting in a typical ‘source pressure’ of  $10^{-6}$ – $10^{-7}$  Torr ( $\sim 10^{-4}$ – $10^{-5}$  Pa), while the other gas flows to waste. Some older mass spectrometers suffered from cross-contamination of the gases due to changeover valve design, necessitating a valve-mixing correction to adjust the measured isotopic composition; this problem has been eliminated in modern designs.

The isotope ratio of interest is obtained by comparing the sample measurement with that from the reference. Actually, several comparisons are made – sample and reference gases are repeatedly and alternately admitted to the mass spectrometer, with analyses taking 10 min and involving 20 or so sample/reference comparisons. Since the sample and reference gases are analyzed identically, there is no need for the mass spectrometer to determine the absolute isotope ratio; the comparative process ensures

## Introduction

The term ‘stable isotope ratio’ in its normal context is restricted to a small group of elements (i.e., hydrogen, carbon, nitrogen, oxygen, and sulfur) that are readily converted into simple gaseous compounds for the purpose of isotope ratio determination using a mass spectrometer. This article will focus on the instrumentation used to measure stable isotope ratios, from dual inlet systems operating with dynamic gas flow through later developments for interfacing to gas chromatography and on to newer static vacuum designs. The fields of application of stable isotope ratio mass spectrometry are broad, transcending the life sciences, atmospheric chemistry, oceanography, agriculture, archaeology, cosmochemistry, geological sciences, etc. In these examples, stable isotopes are used, among other things, to elucidate metabolism, the sources of materials, to constrain the extent of chemical reactions, monitor diffusion, assess formation temperatures, and so on.

## Dual Inlet Mass Spectrometry

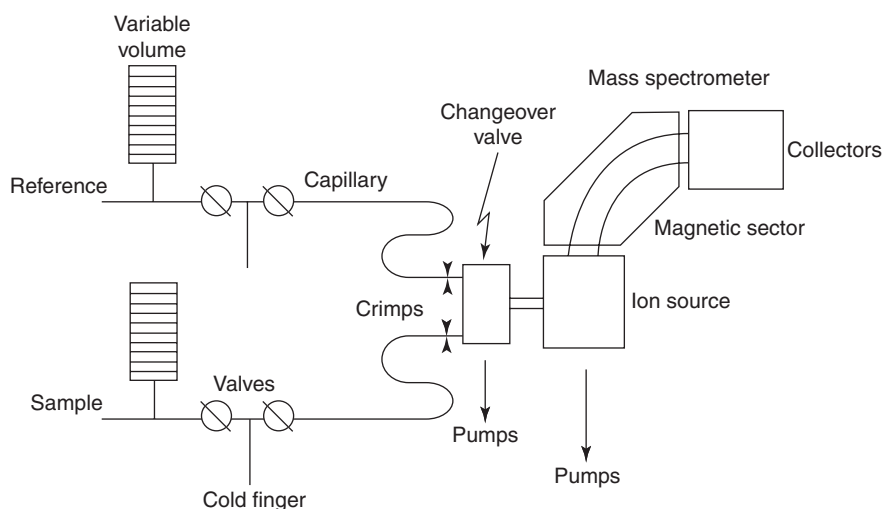

Dual inlet mass spectrometers designed for the purpose of analyzing gas samples were first built in the 1940s. Despite improvements in hardware components such as power supplies, electronic detection systems, and computer control, the modern commercially available mass spectrometer resembles its

forebears in many respects. A schematic diagram of a typical dual inlet mass spectrometer is shown in **Figure 1**. There are two identical inlets, one containing a sample gas of unknown isotopic composition and one containing a reference gas.

Each inlet consists of a variable volume, a cold finger, and a capillary crimped near to its termination. Both inlets are connected to a changeover valve mounted in close proximity to the ion source of the mass spectrometer, which is pumped to a ‘background pressure’ of  $<10^{-10}$  Torr ( $\sim 10^{-8}$  Pa; 1 Torr  $\sim 133$  Pa).

Sample and reference gases, stored at relatively high pressures in each of the inlets, flow continuously through the capillaries and into the changeover valve. At the end of each capillary a crimp allows fine-scale adjustment of flow rate (a procedure carried out only once, when the instrument is first commissioned). The changeover valve selects one of the gases for entry to the mass spectrometer, resulting in a typical ‘source pressure’ of  $10^{-6}$ – $10^{-7}$  Torr ( $\sim 10^{-4}$ – $10^{-5}$  Pa), while the other gas flows to waste. Some older mass spectrometers suffered from cross-contamination of the gases due to changeover valve design, necessitating a valve-mixing correction to adjust the measured isotopic composition; this problem has been eliminated in modern designs.

The isotope ratio of interest is obtained by comparing the sample measurement with that from the reference. Actually, several comparisons are made – sample and reference gases are repeatedly and alternately admitted to the mass spectrometer, with analyses taking 10 min and involving 20 or so sample/reference comparisons. Since the sample and reference gases are analyzed identically, there is no need for the mass spectrometer to determine the absolute isotope ratio; the comparative process ensures

**Figure 1** Dual inlet isotope-ratio mass spectrometer. The instrument is shown as a magnetic sector device with a 90° deflection angle. The mass spectrometer is operated in a dynamic mode, i.e., continuously open to the pumps.

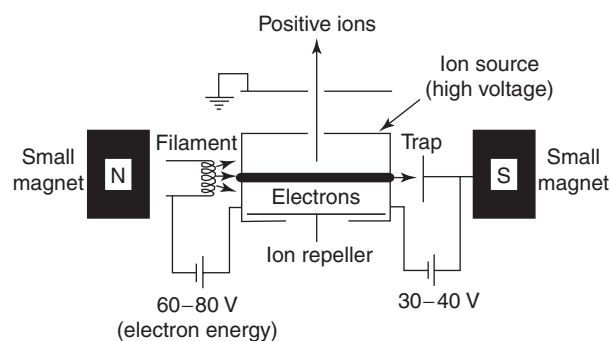

measurements of the appropriate accuracy. High levels of precision result from repeating the comparative procedure many times, this is important since tremendous significance may ultimately be attached to relatively small isotopic variations.

The operating protocol of the dual inlet ensures that when the flow rates of the two gases are equalized, by having equivalent pressures, any accompanying isotopic fractionations are the same in each case, and so the effects cancel out. In order to equalize the pressures of gases in both inlets, either one, or two, variable volumes are used to compress the gas(es) until identical source pressures are obtained. The variable volumes are usually stainless steel bellows, which can be mechanically opened or closed under computer control allowing very accurate 'balancing' of the source pressures. The balancing process is assessed by comparing the magnitude of two parameters for each gas – the source pressure and the intensities of the 'major' ion beams (i.e., those from the isotopically most abundant species, e.g.,  $^{12}\text{C}^{16}\text{O}^{16}\text{O}^+$  in the case of carbon dioxide). An instrument known to be operating satisfactorily will give similar major ion beam intensities, as measured by the mass spectrometer, for equivalent source pressures of sample and reference gases. Any discrepancy implies that one of the gases is contaminated, a situation that could result in a spurious isotope ratio measurement. The instrument itself can be used to assess whether contaminants are present by determining the mass spectrum of the gases in each inlet. The variable volume is potentially wasteful and dual inlet instruments generally incorporate cold fingers for the cryogenic concentration of the gases of interest. This allows measurements of the isotopic composition on 100 nmol quantities of gas.

The selected gas is ionized on entry into the mass spectrometer and the resultant ions separated according to their mass-to-charge ( $m/z$ ) ratio. Ionization is normally effected via an electron impact source of 'closed' design, whereby the flowing gas is admitted to a small box in the mass spectrometer ion source (the ion source is not completely closed; a small conductance to the pump ensures an equilibrium pressure is reached as gases flow into the device). This arrangement results in a greater sensitivity of the instrument since a localized high pressure is obtained in the ion source, which in turn results in more intense ion beams. Too high a source pressure can result in an unwanted ion-molecule reaction, producing the  $\text{H}_3^+$  ion, which causes interference at the masses detected during hydrogen isotope ratio measurement. In this case, it may be necessary to employ an ion source of more traditional, 'open' design, or to decrease the flow rate.

A schematic diagram of an ion source is shown in **Figure 2**. Regardless of type (open or closed), the ionizing electrons are provided by a heated filament, generally tungsten, or thoriated-iridium coated on tungsten. A 3–5 A current boils electrons off the filament by thermionic emission, which are drawn into the ion source by a 60–80 V potential difference between the filament and the rest of the ion source (referred to as the electron energy, typically 70 eV).

A further voltage difference, between the ion source and the trap plate (see **Figure 2**), produces a partially collimated electron beam. Electronic circuitry ensures that the trap current remains at a constant, preselected value (typically 100–1000  $\mu\text{A}$ ). Thus, any changes in filament current due to aging, or the effect of gas being admitted to the ion source, are counteracted by the preservation of a constant

**Figure 2** Typical electron impact ion source configuration for a stable isotope ratio mass spectrometer.

trap current. Small magnets produce a magnetic field parallel to the direction of the electron beam, increasing the effective path length by causing the electrons to spiral. The ion source is operated at a positive voltage of 2–5 kV above the ground potential. Thus, when an electron interacts with a neutral gas molecule and produces a positively charged ion this is ejected from the ion source and subsequently enters the magnetic field region of the mass spectrometer.

An isotope ratio measurement is derived from a determination of the relative intensities of the ion beams as registered at the detector(s). Since the ion beams are due to nuclides that differ in mass by approximately one, the mass resolution does not need to be greater than  $\sim 100$  Da. Thus, stable isotope ratio mass spectrometers are generally small, comprising a magnet that produces a flight path of the ions of the order of 6–12 cm radius, with a deflection angle of  $60^\circ$  or  $90^\circ$ . Typical ion beam intensities are generally greater than  $10^{-12}$  A; therefore, stable isotope ratio mass spectrometers do not require high-gain devices such as electron multipliers. Faraday bucket-type detectors referred to normally as a ‘collector’ are sufficient. Almost all stable isotope ratio mass spectrometers are fitted with multiple collectors capable of measuring the desired ion beams simultaneously. In the case of carbon dioxide, the three ion beams of interest are at  $m/z$  44 ( $^{12}\text{C}^{16}\text{O}^{16}\text{O}^+$ ),  $m/z$  45 ( $^{13}\text{C}^{16}\text{O}^{16}\text{O}^+$ ,  $^{12}\text{C}^{16}\text{O}^{17}\text{O}^+$ ), and  $m/z$  46 (predominantly  $^{12}\text{C}^{16}\text{O}^{18}\text{O}^+$ ). The use of multiple collectors reduces the analysis time and circumvents the problem of instability in the instrument following a ‘peak jumping’ routine, whereby the ion beams of interest are successively focused onto a single collector (i.e., by changing the magnitude of the accelerating voltage, or the magnetic field strength). Some older stable isotope ratio mass spectrometers intended for carbon dioxide analysis may only have two collectors although there are three ion beams that need to be detected. In this case it is necessary to peak-jump in order to measure the appropriate ion

**Table 1** Relative abundances on Earth of the stable isotopes used in stable isotope ratio mass spectrometry

Element	Isotope	Relative abundance (%)
Hydrogen	$^1\text{H}$	99.9844
	$^2\text{H}$ (D)	0.0156
Carbon	$^{12}\text{C}$	98.89
	$^{13}\text{C}$	1.11
Nitrogen	$^{14}\text{N}$	99.64
	$^{15}\text{N}$	0.36
Oxygen	$^{16}\text{O}$	99.7630
	$^{17}\text{O}$	0.0375
	$^{18}\text{O}$	0.1995
Sulfur	$^{32}\text{S}$	95.02
	$^{33}\text{S}$	0.75
	$^{34}\text{S}$	4.21
	$^{36}\text{S}$	0.02

beam ratios, which results in a doubling of the analysis time and, correspondingly, isotope ratio measurements that are not as precise as those obtained from instruments with three collectors. Stable isotope ratio instruments are intended for the analysis of individual, uncomplicated gas species, such as carbon dioxide. Thus, as long as the less intense (minor) beams are adequately focused and collected, the major ions can essentially just be directed toward a wide collector (i.e., there will not be any interfering ions from other species to contribute to the signal).

Each detector is connected to a high-gain amplifier mounted immediately outside the high-vacuum chamber of the mass spectrometer. In sophisticated designs these amplifiers are mounted in their own vacuum chamber (at  $\sim 10^{-3}$  Torr), which helps to stabilize the environmental conditions surrounding the amplifiers and reduces instability in the measured ion beam signal. The amplifiers convert the small ion currents into dc voltages ( $\sim 0.1$ – $10$  V), which can then be further amplified if necessary, processed by an analog-to-digital converter, and read into a desktop computer. More recently, quadrupole instruments have also been used for isotope ratio measurements.

The gases that are normally used for making isotopic measurements are  $\text{H}_2$  (for the D/H, or  $^2\text{H}/^1\text{H}$ , ratio),  $\text{CO}_2$  (for  $^{13}\text{C}/^{12}\text{C}$  and  $^{18}\text{O}/^{16}\text{O}$ ),  $\text{N}_2$  ( $^{15}\text{N}/^{14}\text{N}$ ), and  $\text{SO}_2$  ( $^{34}\text{S}/^{32}\text{S}$ ). In some instances, it is desirable to analyze gases such as  $\text{O}_2$  ( $^{17}\text{O}/^{16}\text{O}$  and  $^{18}\text{O}/^{16}\text{O}$ ) or  $\text{SF}_6$  ( $^{34}\text{S}/^{32}\text{S}$ ,  $^{33}\text{S}/^{32}\text{S}$ ,  $^{36}\text{S}/^{32}\text{S}$ ). A list of the natural abundances of the various isotopes is given in Table 1.

In principle, it should be possible to design a mass spectrometer capable of analyzing all the above gases, i.e., there are no special requirements in terms of the materials used to construct the instrument (although for  $\text{SF}_6$  it is necessary to determine masses of  $\sim 130$ , the parent ion being  $\text{SF}_5^+$ ). In reality, since the various gases may have different requirements in

terms of gas inlets, or instrumental operating conditions, it is commonplace for individual instruments to be dedicated to the analysis of single gas species. Constraints imposed by gas extraction systems lead to sulfur isotope analyses being carried out on dedicated sulfur dioxide instruments. Nitrogen too needs specialized treatment because of the obvious possibilities of atmospheric contamination. A carbon dioxide machine, on the other hand, is able to measure both carbon and oxygen isotopic compositions. Since a major interest in oxygen isotope analyses arises from studies of water samples, there is a demand that any facility capable of analyzing oxygen should also be able to measure hydrogen isotopes as well. In the past this was resolved by the use of a 'Siamese' head, i.e., two mass spectrometer flight tubes (one for carbon dioxide, the other for hydrogen) with only the one dual inlet. More recently, the problem has been circumvented by the evolution of the 'split' flight tube that allows carbon dioxide and hydrogen to be admitted to a single mass spectrometer, the magnetic sector being configured to accept ion beams from either species. Any compromise in the precision to which the D/H ratio can be measured under these circumstances is outweighed by the relatively large range in hydrogen isotopic compositions that exist in nature.

As stated above, the isotope ratio measurements are made by comparing the ion beam intensities obtained from an unknown sample gas with those from a reference gas. In the case of nitrogen, which in the gaseous form exists as the diatomic molecule  $N_2$ , and which has only two stable isotopes ( $^{14}N$  and  $^{15}N$ ), the isotope ratio measurement is made simply by a comparison of sample and reference ion beams at  $m/z$  29 and 28 (i.e.,  $^{14}N^{15}N^+$  and  $^{14}N^{14}N^+$ ). In a more complicated molecule such as carbon dioxide it is necessary to consider both the stable isotopic composition of carbon (which has isotopes  $^{12}C$  and  $^{13}C$ ) and oxygen ( $^{16}O$ ,  $^{17}O$ , and  $^{18}O$ ). Thus, a  $^{13}C/^{12}C$  measurement cannot simply be made by analyzing the ion beams at  $m/z$  45 ( $^{13}C^{16}O^{16}O^+$ ) and  $m/z$  44 ( $^{12}C^{16}O^{16}O^+$ ) since the former beam partly consists of  $^{12}C^{16}O^{17}O^+$ . Thus, it is always necessary to make an oxygen isotopic determination as well (by measuring  $m/z$  46) so that a correction can be applied to the measured  $m/z$  44/45 ratio.

### Isotope Ratio Measurements, Atomic Percentage Enrichments, the $\delta$ Value, and Precision

In their most straightforward usage, isotope ratio mass spectrometers are used to detect artificially

enriched isotopic components as they are introduced into a microenvironment of some description. For instance, isotopically labeled components (normally enriched in heavy isotopes, e.g., D,  $^{13}C$ ,  $^{15}N$ ) may be administered to living organisms in an attempt to trace metabolic pathways. In this case it may not always be necessary to determine the isotope ratio to a high degree of precision and it is customary to quote measured values according to their atomic enrichments, as follows:

$$\text{Atomic \%} = 100/(1 + 1/R)$$

where  $R$  is the ratio of the heavy isotope to the light isotope. Note that for the elements considered herein, the heavy isotopes are always of lesser abundance than the lightest one (this is not true of all elements of course). In the case of carbon a typical value of  $R$  ( $^{13}C/^{12}C$ ) in the terrestrial environment is 0.0112; thus, the atomic percentage of  $^{13}C$  is  $\sim 1.11\%$ . In the same way, a measurement of  $^{13}C$ -enriched material (i.e., elevated  $^{13}C/^{12}C$  ratio) can be quoted in terms of its atomic percentage enrichment and compared with the typical terrestrial value.

In more sophisticated uses of isotope ratio mass spectrometry, the objective will be to detect the relatively small differences in isotopic composition that may exist (1) between different natural occurrences of an identical compound, or (2) when an element is partitioned between two constituents of a natural system. The hydrogen and oxygen isotopic compositions of natural water samples are an example of type (1). On the other hand, type (2) is exemplified by studies that aim to determine the oxygen isotopic composition of calcium carbonate deposited by living marine organisms; knowing the difference in oxygen isotopic composition between carbonate and seawater enables calculation of the temperature of formation. By analyzing fossilized organisms it is possible to document historical variations in temperature.

In studies that require measurement of relatively minor variations in isotopic compositions, it is necessary for the analyses to have errors that are small compared with the anticipated range. Since isotopic variations in natural systems are sometimes quite limited, differences are quoted in per mil (parts per 1000) rather than percent (parts per 100). The symbol for per mil is ‰, where 10‰ is equivalent to 1%. The precision needed for isotopic measurements is generally less than  $\pm 1\%$ , and more probably of the order of  $\pm 0.1\%$ . Note that the ultimate precision possible using a dual inlet mass spectrometer is of the order of  $\pm 0.05\%$ .

Isotope ratios are quoted as per mil variations from a reference point according to the following

formula:

$$\delta \text{ (in ‰)} = \left( \frac{R_{\text{Sam}}}{R_{\text{Ref}}} - 1 \right) \times 1000$$

where  $R_{\text{Sam}}$  is the ratio of heavy to light isotope in the sample and  $R_{\text{Ref}}$  is the equivalent ratio in a reference material. Thus, for example, in the case of carbon, where  $R = {}^{13}\text{C}/{}^{12}\text{C}$ ;

$$\delta^{13}\text{C} = \left( \frac{({}^{13}\text{C}/{}^{12}\text{C})_{\text{Sam}}}{({}^{13}\text{C}/{}^{12}\text{C})_{\text{Ref}}} - 1 \right) \times 1000\text{‰}$$

To facilitate the  $\delta$  values being discussed in an international forum it is necessary to cross-calibrate the data obtained from individual laboratories. This is accomplished by knowing the  $\delta$  value of each laboratory's reference material relative to an internationally accepted standard. The standards used for stable isotopic measurements are given in Table 2. In the case of carbon, where the standard is Pee Dee belemnite (PDB),

$$\delta^{13}\text{C}_{\text{PDB}} = \left( \frac{({}^{13}\text{C}/{}^{12}\text{C})_{\text{Sam}}}{({}^{13}\text{C}/{}^{12}\text{C})_{\text{PDB}}} - 1 \right) \times 1000\text{‰}$$

Since, in this particular case, there is none of the PDB standards remaining, the  $\delta^{13}\text{C}_{\text{PDB}}$  value of an unknown sample is obtained from:

$$\delta^{13}\text{C}_{\text{Sam-PDB}} = \delta^{13}\text{C}_{\text{Sam-Ref}} + \delta^{13}\text{C}_{\text{Ref-PDB}} + \frac{\delta^{13}\text{C}_{\text{Sam-Ref}} \times \delta^{13}\text{C}_{\text{Ref-PDB}}}{1000}$$

where  $\delta^{13}\text{C}_{\text{Sam-Ref}}$  is the measurement of the unknown sample relative to the reference, and  $\delta^{13}\text{C}_{\text{Ref-PDB}}$  is the value for the reference relative to PDB (a datum that may have been derived in the past when PDB was still in evidence, or via other reference materials). Appropriate reference materials are available from the National Institute of Standards and Technology (Gaithersburg, Maryland, USA).

## Gas Preparation Techniques

In all but a few cases it is necessary to convert the material under investigation into a gas for stable isotope mass spectrometric measurement. Even if the element already exists in the appropriate form (e.g.,  $\text{CO}_2$  trapped in ice cores, or as the product of respiration) purification may still be necessary. It is impossible to list full details of all gas extraction procedures here and, as such, only a brief outline is given for each element. Hydrogen isotopic compositions are derived from hydrogen ( $\text{H}_2$ ) gas; this is generally obtained via the reduction of water, using heated uranium or zinc. Sample waters thus require only minimal preparation, whereas hydrogen from more refractory sources is converted to water either by direct heating (pyrolysis), or under an atmosphere of oxygen (combustion). For carbon, the analysis gas is carbon dioxide,  $\text{CO}_2$ . This can be obtained by combustion techniques or, as in the case of carbonate analyses, reaction of the mineral with acid to produce  $\text{CO}_2$ . Nitrogen is prepared either by combustion, pyrolysis, or, in the case of organic materials, a more complex technique known as the Kjeldahl method. A particular problem for nitrogen is to ensure that no gaseous oxides are formed during the preparation procedure. Oxygen isotopic compositions of carbonates are prepared by acid treatment (as in the case of carbon) whereas the oxygen in water samples is measured by an isotopic equilibration procedure involving  $\text{CO}_2$ . In order to determine the oxygen isotopic composition of a silicate rock sample, the minerals are treated with a fluorinating agent (such as  $\text{F}_2$ ,  $\text{ClF}_3$ , or  $\text{BrF}_5$ ), which displaces the oxygen, producing  $\text{O}_2$  gas. This is then either measured directly, or converted to  $\text{CO}_2$  by reaction with graphite. Sulfur bearing constituents are generally separated and combusted to  $\text{SO}_2$ , or fluorinated to produce  $\text{SF}_6$ .

In all the above procedures it is necessary to purify the gases prior to analysis. This is accomplished by chemical, or cryogenic, means. The pressure of the purified gas can then be measured, for quantification

**Table 2** Reference materials used for making stable isotope ratio measurements

Element	Reference	Isotopes	Absolute ratio	Comments
Hydrogen	SMOW	D/H	$1.5576 \times 10^{-4}$	Standard mean ocean water (an artificial standard closely representing sea water)
Carbon	PDB	${}^{13}\text{C}/{}^{12}\text{C}$	$1.12372 \times 10^{-2}$	Pee Dee belemnite ( <i>Belemnitella Americana</i> , a fossil from S. Carolina, USA)
Nitrogen	AIR	${}^{15}\text{N}/{}^{14}\text{N}$	$3.67647 \times 10^{-3}$	Atmospheric nitrogen (known to be isotopically homogeneous)
Oxygen	SMOW	${}^{18}\text{O}/{}^{16}\text{O}$	$2.0052 \times 10^{-3}$	Standard mean ocean water (also use PDB for carbonate studies)
		${}^{17}\text{O}/{}^{16}\text{O}$	$3.8288 \times 10^{-4}$	
Sulfur	CDT	${}^{34}\text{S}/{}^{32}\text{S}$	$4.50045 \times 10^{-2}$	Canyon Diablo Troilite ( $\text{FeS}$ from an iron meteorite)
		${}^{33}\text{S}/{}^{32}\text{S}$	$8.09976 \times 10^{-3}$	
		${}^{36}\text{S}/{}^{32}\text{S}$	$1.79058 \times 10^{-4}$	

purposes, following which it is admitted to the mass spectrometer. The laborious and time-consuming nature of gas preparation has led to the development of certain automated gas-extraction techniques (e.g., batch combustion, multiple sample acid dissolution devices, etc.). On a more research-orientated front, the laser microprobe uses a focused laser beam ( $\sim 50\text{ }\mu\text{m}$ ) to heat a localized area of the sample of interest. The benefits of this technique lie in its inherent rapidity and also the low associated blank levels. Laser pyrolysis has been used successfully to liberate nitrogen from various samples, and to deprecipitate carbonates to  $\text{CO}_2$  gas. When laser heating is carried out under a pressure of oxygen, it is possible to conduct microscale combustion. A further implementation involves using a laser beam in conjunction with a fluorinating agent to allow oxygen isotopic analyses of small quantities of silicate samples.

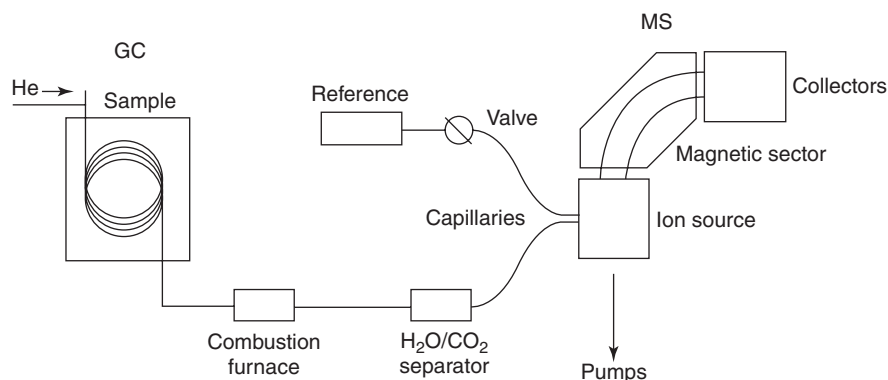

## Gas Chromatography–Isotope Ratio Mass Spectrometry

Stable isotope ratio mass spectrometers that interface directly to a gas chromatograph are commercially available. This type of analysis is known variously as gas chromatography–isotope ratio mass spectrometry (GC–IRMS), gas chromatography–combustion isotope ratio mass spectrometry, or compound-specific isotope analysis. The same principle of operation has also been used for more general isotope ratio analyses, where the components of interest are combusted as bulk samples. This type of arrangement, known as continuous flow–isotope ratio mass spectrometry, allows rapid automated analyses of  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ .

The mass spectrometers used for GC–IRMS have dual inlets, although in this case there are no

changeover valves (see **Figure 3**). Rather, a flow of helium gas through two capillaries transports small quantities of sample and reference gases into the mass spectrometer ion source. Complex mixtures of organic compounds are injected into a capillary column gas chromatograph and then separated according to normal principles. Each compound is then swept through a combustion furnace (comprising copper oxide and a platinum catalyst, operated at a temperature of  $\sim 800^\circ\text{C}$ ) where it is converted to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  (and  $\text{N}_2$ , if the compounds are nitrogen bearing). In principle, it should be possible, using GC–IRMS, to make stable isotope ratio measurements of hydrogen, carbon, and nitrogen; oxygen is excluded since, under these circumstances, it arises from the combustion furnace. Considerable successes have been achieved with the determination of carbon and nitrogen isotope ratios using GC–IRMS.

An immediate problem that has to be addressed regarding the mass spectrometry in a GC–IRMS system is the separation of  $\text{N}_2$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  out of a flowing stream of gas. This is accomplished in practice by various means, including cryogenic removal, and/or the use of water-permeable membranes. Purified  $\text{N}_2$  or  $\text{CO}_2$  is then carried into the ion source of the mass spectrometer using the flow of helium. The flow of carrier gas into the mass spectrometer results in higher source pressures and turbo-molecular pumps provide a higher pumping capacity than that used for dual inlet machines. In other respects the operation of the ion source and mass spectrometer can be considered similar to the conventional case. A fundamental difference is that the ion beam intensities for an individual  $\text{N}_2$  or  $\text{CO}_2$  sample can be measured for only a brief period of time (a few seconds). Furthermore, since there is an isotopic fractionation associated with the flowing gas, the measured isotopic composition changes markedly

**Figure 3** Gas chromatography–isotope ratio mass spectrometer (GC–IRMS). The mass spectrometer (MS) depicted here is similar in many respects to that shown in **Figure 1**. The instrument operates on a dynamic principle, although in this case the capillaries are not connected to a changeover valve.

during the course of analysis. In order to combat this effect it is necessary to integrate the ion beam yields obtained for each isotopic species during the analysis. It goes without saying that multiple collections are essential since there is no time available for peak jumping.

The sensitivity of the GC-IRMS system is very high compared with a normal dual inlet mass spectrometer. It has been shown that isotope ratio measurements of carbon in 100 pmol samples of  $\text{CO}_2$  can be measured to precisions of  $\pm 0.5\%$ . The level of precision is limited by the sample size and also by the nature of the operation of the GC-IRMS. Because eluted compounds are continuously flowing from the gas chromatograph column and into the combustion furnace, it is not possible to derive the isotopic measurements from rapid and repeated sample/reference comparisons, as in the case of a dual inlet mass spectrometer. Thus, it is generally only possible to contemplate an analysis of a reference gas at the beginning, or end, of a run (or preferably both). Under normal circumstances this is affected by admitting an aliquot of reference gas (of, say, 1–10 nmol) into the mass spectrometer via the second capillary. This gas is swept into the ion source by its own stream of helium carrier gas and analyzed in the same way as gases produced by the combustion furnace. If an aliquot of reference gas is analyzed before and after the sequence of combusted organic compounds elutes from the gas chromatograph, the results serve as a check on the stability of the instrument over this time period. It is then possible to derive  $\delta$  values for individual compounds by comparing ion beam intensities with those obtained from the reference gas at the start and end of the run. In order to obtain results of the highest precision it is desirable to calibrate the instrument with respect to the compounds under investigation. This is carried out by injecting reference compounds of known isotopic compositions into the gas chromatograph and measuring the isotopic compositions of the gases produced by the combustion furnace. Ideally, these reference compounds need to have isotopic compositions that are similar to the unknown samples under investigation.

## Static Mass Spectrometry

The GC-IRMS system achieves its high level of sensitivity by virtue of the fact that the entire gas sample is admitted to the mass spectrometer for analysis. However, because the mass spectrometer operates dynamically, the small quantities of gas that enter the ion source are very quickly pumped away (i.e., the gas may flow through the ion source for only a few

**Figure 4** Static isotope ratio mass spectrometer. The mass spectrometer depicted here, which is similar in many respects to that shown in **Figure 1**, is isolated from the pumping system during the analysis, by means of closing a valve, P (i.e., a static mode of operation).

seconds). An alternative approach to the analysis of small samples of gas is to use a static vacuum mass spectrometer (see **Figure 4**) where the entire sample (or a portion thereof contained between valves 1 and 2) is admitted to the instrument after it has been isolated from the pumps.

This is essentially the way in which isotopic compositions of noble gases are measured, where the unreactive species are able to remain in the static vacuum for long periods of time, the only losses being due to ionization and subsequent implantation. In contrast, 'active' gases have certain special problems, not least of all because they may undergo reactions within the mass spectrometer during analysis. Furthermore, gases may leak from the surrounding air into the high vacuum of the instrument; there may also be outgassing effects. Notwithstanding these problems, static mass spectrometers have been successfully used to analyze gases such as  $\text{CH}_4$ ,  $\text{CO}_2$ , and  $\text{N}_2$ . Thus so far it has proved possible to measure carbon and nitrogen isotope ratios routinely using static mass spectrometry; furthermore, it has been demonstrated that oxygen and hydrogen isotopic measurements are also feasible.

A static mass spectrometer only has a single inlet and no changeover valve. The required  $\delta$  value is obtained by comparing the ion beam intensities of the unknown sample with aliquots of a reference gas admitted to the instrument before and after the sample. Since it is essential to pump the mass spectrometer to high vacuum ( $\sim 10^{-10}$  Torr) after each analysis, the total time required to produce one  $\delta$  value is  $\sim 30$  min. Notwithstanding any instabilities that may operate over this timescale, precisions in  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  of  $\pm 0.5\%$  can be obtained routinely

using static mass spectrometry, from measurements of 100 pmol quantities of CO<sub>2</sub> and N<sub>2</sub>. Furthermore, the instruments' potential capabilities have been demonstrated down to the level of 10 pmol.

The techniques used to prepare the gases for analysis are essentially the same as those used for dual inlet mass spectrometry although a major consideration here is the blank levels that are incurred. Because of current blank limitations static mass spectrometry is normally restricted to investigations at the level of 0.1–1 nmol although the advent of new methods of gas extraction, such as the laser microprobe technique, may circumvent this problem.

## Introduction

Pyrolysis mass spectrometry (PyMS) is a sensitive analytical technique in which samples are subjected to rapid thermal degradation (pyrolysis) before the derivative ions are separated in a mass spectrometer. The technique is particularly suitable for the analysis of otherwise nonvolatile compounds in complex samples. Pyrolysis causes the weakest bonds in each molecule to break, forming volatile fragments (the pyrolysate) whose masses are expressed as a pyrolysis mass spectrum. This can be interpreted and used to characterize the structures of the parent molecules in the sample, or used in an uninterpreted manner to provide a diagnostic fingerprint that can easily distinguish between related complex samples, such as different microbial strains. Quantitative analysis is possible using sophisticated statistical methods based on neural networks and supervised learning, making PyMS useful for a very wide variety of applications.

Two critical aspects of the technique are the requirement for rapid and reproducible heat input, so

that degradation occurs in the context of a steep thermal gradient, and the need to remove primary degradation products from the pyrolysis zone immediately after they are formed. Under these circumstances, the primary pyrolysis events can be described as instantaneous, and secondary events (such as further degradation and recombination between primary fragments) can be avoided. Additionally, the time constant of the analysis should ideally be compatible with that of the degradation process itself. The coupling of *in vacuo* Curie-point pyrolysis (see below) with high-speed quadrupole or ion-trap mass spectrometry achieves all of these requirements, and is therefore the most widely practiced form of PyMS today. Curie-point pyrolysis is also the basis of all commercially available PyMS instruments.

## Development and Instrumentation

### Early Development

The origins of PyMS can be traced back to 1952, when Zemany first investigated the use of thermal degradation products for the characterization of biopolymers. In these initial experiments, the pyrolysis step was carried out offline and the pyrolysate was

using static mass spectrometry, from measurements of 100 pmol quantities of CO<sub>2</sub> and N<sub>2</sub>. Furthermore, the instruments' potential capabilities have been demonstrated down to the level of 10 pmol.

The techniques used to prepare the gases for analysis are essentially the same as those used for dual inlet mass spectrometry although a major consideration here is the blank levels that are incurred. Because of current blank limitations static mass spectrometry is normally restricted to investigations at the level of 0.1–1 nmol although the advent of new methods of gas extraction, such as the laser microprobe technique, may circumvent this problem.

## Introduction

Pyrolysis mass spectrometry (PyMS) is a sensitive analytical technique in which samples are subjected to rapid thermal degradation (pyrolysis) before the derivative ions are separated in a mass spectrometer. The technique is particularly suitable for the analysis of otherwise nonvolatile compounds in complex samples. Pyrolysis causes the weakest bonds in each molecule to break, forming volatile fragments (the pyrolysate) whose masses are expressed as a pyrolysis mass spectrum. This can be interpreted and used to characterize the structures of the parent molecules in the sample, or used in an uninterpreted manner to provide a diagnostic fingerprint that can easily distinguish between related complex samples, such as different microbial strains. Quantitative analysis is possible using sophisticated statistical methods based on neural networks and supervised learning, making PyMS useful for a very wide variety of applications.

Two critical aspects of the technique are the requirement for rapid and reproducible heat input, so

that degradation occurs in the context of a steep thermal gradient, and the need to remove primary degradation products from the pyrolysis zone immediately after they are formed. Under these circumstances, the primary pyrolysis events can be described as instantaneous, and secondary events (such as further degradation and recombination between primary fragments) can be avoided. Additionally, the time constant of the analysis should ideally be compatible with that of the degradation process itself. The coupling of *in vacuo* Curie-point pyrolysis (see below) with high-speed quadrupole or ion-trap mass spectrometry achieves all of these requirements, and is therefore the most widely practiced form of PyMS today. Curie-point pyrolysis is also the basis of all commercially available PyMS instruments.

## Development and Instrumentation

### Early Development

The origins of PyMS can be traced back to 1952, when Zemaný first investigated the use of thermal degradation products for the characterization of biopolymers. In these initial experiments, the pyrolysis step was carried out offline and the pyrolysate was

introduced manually into the mass spectrometer. Even so, it was shown that the thermal degradation products of proteins such as albumin yielded reproducible molecular fingerprints that, in principle, could be used to identify these proteins in other samples.

Throughout the 1950s and 1960s, there were continuing developments in pyrolysis techniques and in the use of mass spectrometry to analyze thermal degradation products. Although many investigators demonstrated the principle of online pyrolysis followed by mass spectrometry, most of the work carried out during this period focused on the use of relatively slow heating methods, which made the pyrolysis conditions difficult to reproduce and did not prevent the occurrence of secondary events. Even rapid heating methods, such as galvanic filament pyrolysis and laser-induced pyrolysis, were found to be difficult to control in the context of PyMS and were shown to induce many competing processes.

The Curie-point pyrolyzer, described by Giacobbo and Simon in 1964, was to provide the key to solving many of these problems. In this method, pyrolysis is achieved by the rapid inductive heating of a ferromagnetic substrate (e.g., a wire or foil) using an electromagnetic coil. The temperature increases steeply and in a linear fashion until the metal reaches its Curie point. When this temperature is achieved, the substrate loses its ferromagnetic properties and inductive heating ceases. However, as soon as the temperature drops below the Curie point, the ferromagnetic properties return and heating resumes. Curie-point pyrolysis, therefore, has the powerful advantage that skin heating rates are constant, e.g., for wires of identical cross-section, in a given electromagnetic field. This means that the heating step is both rapid and highly reproducible, two of the most important requirements for analytical PyMS. Furthermore, the use of wires or other disposable metal holders means that each pyrolysis event can be carried out on a clean surface, reducing the likelihood of cross-contamination between samples.

The first meaningful study involving Curie-point PyMS was published in 1970, and dealt with the analysis of dyes, fatty acid derivatives, and substituted benzoic acids. The apparatus used in this study consisted of a Curie-point pyrolyzer coupled to a magnetic sector mass spectrometer by means of a short length of capillary tubing. The tubing led from the pyrolyzer to a conventional molecular separator positioned in front of the ionization chamber. This instrument became the benchmark for future developments in PyMS and led directly to the introduction of the first automated Curie-point pyrolysis mass spectrometer in 1973.

### Later Development: Automated PyMS

From 1970 onwards, most of the impetus for further developments in PyMS instrumentation was confined to a group working at the FOM-Institut in Amsterdam. In 1973, Meuzelaar and Kistemaker described the differentiation of bacterial strains using PyMS. They developed an instrument in which the pyrolyzer was integral with the vacuum system of a high-speed quadrupole mass spectrometer, and was connected directly into an electron-impact ionization source operating in low-voltage mode so that the emerging pyrolysis products would be ionized but not subject to further fragmentation. The ionization source was connected to the quadrupole by means of a heated, gold-plated expansion chamber, which was surrounded by a liquid-nitrogen-cooled screen to condense out neutrals and prevent them fouling the mass analyzer. From there, it was a short step to the design and construction of a fully automated system (**Figure 1**) in which a rotary magazine of 40 sample wires in glass carriers (**Figure 2**) was loaded into the extended vacuum system of the quadrupole instrument. The coated sample wires, in their protective glass carriers, were automatically introduced into the pyrolysis zone and heated sequentially. A series of mass scans over the appropriate mass range was then recorded.

Further notable developments include renewed interest in the use of laser source pyrolysis, particularly in combination with time-of-flight mass spectrometry, which offers the possibility of targeting particular chemical bonds for degradation, and the coupling of analytical pyrolysis and tandem mass spectrometry, to induce the fragmentation of specific pyrolysate ions. The latter has culminated in the construction of a number of novel instruments, including a pyrolysis ion trap mass spectrometer capable of MS<sup>n</sup> analysis.

### Overview of the PyMS Method

Correct sample preparation and presentation are very important factors for the accuracy of PyMS, and sample preparation in quadruplicate is often carried out to ensure reproducibility. Samples readily soluble in a volatile solvent cause few problems other than a tendency to bead. Thin films are required to avoid primary degradation products diffusing through the undegraded or partially degraded sample, which presents an opportunity for secondary events. Beading can be avoided by adding a small amount of tetrahydrofuran or dioxan to the sample, since these substances act as wetting agents. Insoluble samples can be ground to powder and dispersed in a volatile liquid before placing on the Curie-point substrate, although care must be exercised to avoid mechanical degradation.

**Figure 1** Schematic section of a pyrolysis mass spectrometer.

**Figure 2** Detail showing sample carrier. (Reprinted with permission from Meuzelaar HLC, Haverkamp J, and Hileman FD (1982) Techniques and instrumentation in analytical chemistry. In: *Pyrolysis Mass Spectrometry of Recent and Fossil Biomaterials*, vol. 3, p. 14. Amsterdam: Elsevier; © Elsevier.)

Biological samples such as microbial cultures must be obtained carefully using disposable plastic wires or picks, and smeared on the Curie-point substrate. If the sample is from a liquid culture, a small amount of liquid is applied directly to the substrate. In each case, the samples are dried by heating in an oven or by vacuum desiccation. The samples are loaded into the instrument sequentially and the pyrolysate is

generated in a vacuum. A radio-frequency current is passed through a pyrolysis coil, which surrounds the Curie-point substrate (**Figure 2**). The substrate reaches its Curie-point temperature within 0.2–0.3 s, and the pyrolysate expands into a gold-plated chamber heated to 150°C, from where it diffuses to the ionization chamber of the mass spectrometer. A common approach with biological samples is to use alloy foils made of equal parts iron and nickel, which have a Curie-point temperature of 530°C. This has been shown to provide a good balance between the fragmentation of carbohydrates and proteins. For other samples, alternative Curie-point substrates can be used. For example, iron/nickel alloys with different ratios of the two metals can be used to achieve Curie-point temperatures of, e.g., 350, 610, and 770°C.

In the mass spectrometer, the pyrolysate is bombarded with low-energy electrons (~25 eV) producing molecular and fragment ions, most of which carry a single charge. The ions are focused and accelerated toward the quadrupole analyzers, where they are separated on the basis of their mass to charge ( $m/z$ ) ratios to generate the mass spectrum. Neutral molecules and fragments are trapped by the

nitrogen-cooled screen and are removed from the instrument.

## Data Analysis in PyMS

### Multivariate Analysis

The major application of PyMS is sample profiling to identify diagnostic fingerprints of particular analytes. In analytical chemistry and geochemistry, where the fingerprints of specific organic molecules are relatively easy to identify, standards can be used as reference profiles to facilitate sample matching to known compounds. In the case of more complex biological samples, where PyMS has been widely used to identify metabolites, adulterants or different microbial species in environmental, biological, and industrial samples, principal component analysis (PCA) is often used to simplify the multivariate data and identify key differences and similarities between samples. The canonical variates analysis (CVA) method is very similar, separating the samples into different categories based on the principal components and some *a priori* knowledge of the appropriate number of groupings. As an example, **Figure 3** shows pyrolysis mass spectra for Ceylonese and African teas, the inversion of the intensities at masses 110 and 111 being one of the most obvious differences between them. **Figure 4** shows the results of CVA procedure, i.e., a map obtained by plotting the first canonical variate against the second, resulting in clustering that is self-evident. For microbial specimens, clustering methods may be used to map the relationships between different samples. The first step is to produce a similarity matrix, which shows the percentage similarity between all possible pairs of samples, and then this is converted into a dendrogram in which the most closely related samples are linked together through the use of hierarchical clustering algorithms. If reference strains are included in this analysis, then unknown isolates can be compared to a variety of known genera and species to increase the likelihood of identification.

In a clinical setting, the multivariate analysis of pyrolysis mass spectra is widely used to identify clinical isolates in a manner that is much more rapid, reliable, and convenient than conventional typing systems. Conventional typing generally involves a battery of specialized culture-based tests to identify the species and determine antibiotic sensitivity. This process is not always specific because a limited range of properties is tested, such as particular markers, cell-surface proteins or metabolic capabilities. It can take more than 3 days to generate sufficient information to enable a rational choice of antibiotic

**Figure 3** Pyrolysis mass spectra of extracts derived from Ceylonese and African teas: (A) Tea Kep (Africa) and (B) Tea Dya (Ceylon). (Reprinted with permission from Vorhees KJ (ed.) (1994) *Analytical Pyrolysis: Techniques and Applications*. London: Butterworths; © Elsevier.)

therapy for a seriously ill patient. PyMS is advantageous in this respect because the entire cell is used to derive the fingerprint, which potentially provides

much more useful information than tests designed to identify individual biological features. Furthermore, while conventional tests for different microbes differ widely in their methodology and the amount of expertise required to perform them, PyMS is a single technique that can be applied to all microbial isolates. The same advantages apply to the identification of microbes in environmental samples or spoiled food, and the identification of novel bacterial strains producing potentially therapeutic compounds. In many ways, PyMS is complementary to the use of DNA analysis for taxonomic assignment, since the latter is also a simple and universal method although based on the analysis of genotype rather than phenotype. Where the two methods have been compared there is often close agreement in the relationships that are identified. For example, studies of *Bradyrhizobium japonicum* and *Clostridium acetobutylicum* isolates using PyMS and 16S rRNA profiling have shown very similar clustering hierarchies.

### Supervised Learning

PCA and other multivariate methods achieve the clustering of related data points so that samples can be grouped together according to similarity. The overall purpose of this type of analysis is to distinguish individual components of the dataset, which means it is difficult or impossible to generate quantitative data. Quantitative interpretations of pyrolysis mass spectra can be achieved using a different approach in which the multivariate spectra are subjected to various types of regression analysis. Several techniques have been applied, including multiple linear regression (MLR), partial least squares regression (PLS) and principal components regression (PCR). These techniques are often grouped under the term 'supervised learning', because the algorithms must be trained using calibration data (spectral standards and training sets), which allow them to predict results from new spectra. Similar methods have been developed using artificial neural networks, which have also been employed to correct for instrumental drift – a phenomenon that reduces long-term reproducibility and makes it difficult to compare samples that have been collected more than a few days apart.

The first use of neural networks for the interpretation of PyMS spectra was reported by Goodacre (see Further Reading) for the identification of adulterated olive oils. The neural network was trained with standard pyrolysis mass spectra from 12 virgin and 12 adulterated olive oils, and then tested against a bank of further samples. The method successfully discriminated between virgin oils and those which had been adulterated with other seed oils, while PCA

and other multivariate techniques failed to do so. Since this initial report, the combination of PyMS and supervised learning methods has been widely used both in the identification of contaminants and adulterants, and in the analysis of microbial isolates (see later).

### Applications of PyMS

PyMS is an extremely versatile analytical method, which has been applied in a wide range of areas including organic and inorganic chemistry, geochemistry, environmental biology, archaeology, forensic science, food analysis, clinical biology, and biotechnology. In geochemistry, PyMS has been used for the analysis of coals, shales, peats, and sediments, but perhaps the most interesting application in this area is in oil exploration, where its ability to detect and characterize volatile hydrocarbons in small pieces of rock, such as drill chips, has greatly enhanced the analysis of cored samples. In archaeology, PyMS has been used to determine how ancient artifacts were used. For example, the examination of pottery fragments and other such items has revealed the presence of sealed-in volatile compounds which allowed the original use of the vessel from which the fragments came to be determined, e.g., wine jugs, food utensils, and oil containers. In another example, PyMS was used to determine the likely purpose of a 20 000-year-old Neolithic Egyptian grinding stone, which had been buried in the sand since the dawn of history.

Many workers have used PyMS to study the structures of polymers, both natural and artificial. Understanding the performance of polymers in terms of cohesion and substrate adhesion is of immense commercial significance in the paint and adhesive industries. Similarly, the behavior of polymers under stress and when exposed to external factors such as ultraviolet light has been extensively studied by PyMS and is useful in the development of novel materials that have desirable properties, e.g., fire-retardant coatings and biodegradable fibers. There is much interest in polyhydroxyalkanoates as potentially biodegradable plastics, and PyMS has been a principal method used to study thermal degradation profiles of this material. Similarly, in forensic science, PyMS has been used to analyze fibers and to help match samples of automotive finishes to paint chips found at crime scenes.

In environmental science, PyMS is used for the identification of microbial isolates (see below) and to study the origins and impact of environmental pollutants. For example, carbon-rich material condensing on airborne particulates adjacent to roads can be positively linked to emissions from traffic plus a

small contribution from the degradation of tires. Samples taken from lake and river sediments, or from the inlet and outlet systems of sewerage plants, can be used to judge the efficiency of sewerage treatment and pollution limitation in factory effluents. PyMS has also been widely applied in the food industry, particularly in quality control and the detection of adulteration. **Figures 3 and 4** show how PyMS can be used to identify the sources of teas, and in similar fashion the technique has been used to authenticate different types of whiskey, olive oil, orange juice, oysters, cheese, and honey. Indeed, PyMS is an ideal method for quality control in a number of bioprocesses including fermentation, metabolic engineering, and the production of recombinant proteins by cultured cells.

In this context, the applications of PyMS in biotechnology are of particular interest. The technique has been used to detect and measure the level of metabolites produced in cell culture, such as indole produced by cultured *Escherichia coli* cells grown in different types of media, and to predict the yield of recombinant protein in culture systems, such as *E. coli* producing recombinant cytochrome B5 or  $\alpha$ -interferon. An analogous application is the use of PyMS to profile drugs and their metabolic breakdown products in serum (e.g., cyclosporin, vancomycin), or to profile microbial isolates for novel drug-producing strains.

However, the major application of PyMS in many areas of biology remains the rapid identification of particular microbes at the genus, species, or subspecies levels. This approach has been used to analyze environmental specimens, clinical specimens, and food samples for the rapid identification of pathogens, spoilage organisms, and the characterization of ecological diversity. Interesting examples include the successful identification of coffee rust spores responsible for the large-scale destruction of coffee crops, the characterization of algal diversity in estuarine environments, the analysis of cell-wall mutants of the yeast *Saccharomyces cerevisiae*, the predication of bacterial populations in different types of yogurt,

and the identification of novel actinobacters in sewerage sludge.

The myriad of applications in diverse fields, coupled with the continuing advances in instrumentation, sensitivity, quantitative analysis, long-term reproducibility, and data-handling methods, will ensure that PyMS plays a crucial role in many analytical settings in the future.

## Introduction

One of the most influential developments in archaeology in the latter part of the twentieth century has been the application of sophisticated analytical

techniques to excavated archaeological material, greatly increasing the range of information that can be derived from archaeological remains at the post-excavational stage. This has enabled archaeologists and archaeological scientists to probe past societies and cultures in greater detail, examining social and economic structures, diet and subsistence, technological development, trade contacts, and sources of wealth. The archaeologically valuable information that can be derived from ancient remains by means of mass spectrometry (MS) falls into three broad categories: provenance, biomolecular studies, and dating.

## Provenance Studies

Archaeological provenance studies – the tracing of artifacts to the source of their raw materials and production – plays an important role in understanding ancient systems of trade and exchange, and the organization of past societies. The quest for provenance is to find a characteristic ‘fingerprint’ unique to a particular raw material source, and to identify that same fingerprint in finished artifacts. Artifacts such as stone axes and coarse pottery can be characterized by optical microscopy, but more homogenous materials such as flint are generally distinguished by trace element composition. Although much of the groundwork for trace element characterization of materials was done prior to its invention, the multielement capability of plasma mass spectrometers has proved useful for the provenance of a range of materials. In some cases, however, the trace element composition of an artifact is changed in its manufacture, or the material is simply too homogenous (or conversely a source too variable) to characterize by trace elements alone. In these cases isotopic analyses can often provide the required ‘fingerprint’.

### Provenance of Marble

The provenance of marble is one such case. Early attempts at provenance using trace elements found that trace element concentrations varied by factors of over 100 within the same quarry. However, the stable isotopic ratios of oxygen and carbon have been used to discriminate between marble sources. These isotopic ratios are fractionated during initial formation of the protolith. For example, the  $\delta^{18}\text{O}$  will vary with the source of the carbonate (a chemical precipitate, or of biogenic origin), and will be further fractionated during metamorphism.  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  are measured using isotope ratio MS, and isotopic databases of values for Early Bronze Age Cycladic marble, and Classical marble exist for the Mediterranean region. In cases where the oxygen and carbon isotope values overlap and sources cannot be discriminated,

$^{87}\text{Sr}/^{86}\text{Sr}$  measured using thermal ionization mass spectrometry (TIMS) can often be successfully used to provide an additional signature. Oxygen and carbon isotopes have also been used to match broken fragments of marble inscriptions, to identify later repairs to statues, and identify probable fake marble sculpture.

### Provenance of Metals Using Lead isotopes

The provenance of metal artifacts provides particular problems, since there are several processing stages from the ore to the finished artifact in which the elemental composition will change. Ores are generally processed before smelting, and two or more ores (along with a flux) can be co-smelted. The resulting metal is often remelted and refined, and potentially alloyed with another metal before the final artifact is produced. Each of these steps can alter the composition of the metal to the point where the trace element composition can be significantly different from the initial ore. However, in general, the lead isotopic composition of an ore is transmitted to the finished metal, and even in the case of the mixing of two metals from different sources, the isotopic ratios will change in a predictable fashion.

The ratios of  $^{208}\text{Pb}/^{206}\text{Pb}$ ,  $^{207}\text{Pb}/^{206}\text{Pb}$ , and  $^{206}\text{Pb}/^{204}\text{Pb}$  in an ore are a function of its geochemical history.  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ , and  $^{208}\text{Pb}$  are the stable products of the radioactive decay series with parent isotopes  $^{238}\text{U}$ ,  $^{235}\text{U}$ , and  $^{232}\text{Th}$ , and will thus be different for deposits of different ages and different radioactive parent compositions. For copper and lead ores with a simple geochemical history, the isotopic ratios of lead can provide a distinct fingerprint by which artifacts can be attributed to that source. However, some ore fields have complex geochemical histories and widely varying isotopic signatures that may overlap with ore deposits from other regions. However, with supporting archaeological evidence (e.g., to eliminate mines that were not in production at a particular time), and provided the known sources of ore are well characterized, copper, lead, and silver artifacts have been attributed to ore sources with only a small degree of uncertainty.

Perhaps the best characterized are the Cypriot copper ore deposits exploited from the second millennium BC. By the Late Bronze Age (LBA), Cypriot mines were providing the ores for the production of large ‘ox-hide’ copper ingots weighing 25–28 kg, which were traded all over the Mediterranean. TIMS lead isotope studies have traced the majority of LBA ox-hide ingots found in the Mediterranean, including those on the Ulu Burun and Gelidonya shipwrecks, to the Apliki ores of Cyprus.

## Biomolecular Studies

The two primary applications of MS to biomolecular archaeology are the study of human diet and life histories using light stable isotopes and trace elements, and the analysis of residues on ceramics and other artifacts.

### Human Diet and Life Histories

Palaeodietary reconstruction using light stable isotopes is based on the principle that 'you are what you eat' – that molecules consumed as food are incorporated into the consumer's body tissues and therefore that a chemical signal passed either unchanged or altered in a quantifiable fashion from food into the body can provide dietary information. The natural variation in the distribution of stable isotopes of carbon, nitrogen, and sulfur throughout different ecosystems makes it possible to use them as natural dietary tracers, whilst oxygen and hydrogen isotopic distributions reflect environmental temperature and water sources, and ratios of radiogenic isotopes such as strontium and lead relate to the local geological environment, and can provide information as to an individual's place of origin.

**Human diet** When interpreted in relation to the isotopic signatures of available food sources, the combination of carbon and nitrogen isotope ratios in archaeological bone provides an objective and direct measure of the diet of an individual (see **Figure 1**). Most of the isotope analyses for palaeodiet are of the bone and tooth protein collagen, since bone is the most abundantly surviving human and animal material on archaeological sites. Collagen also has the significant advantage of being chemically characterizable, independent of the isotope measurement, which allows an assessment of the integrity of the material being analyzed, and affords confidence that the signal being measured is biogenic in origin rather than diagenetic contamination. The carbonate fraction of bone and tooth mineral can also be analyzed, and though prone to contamination in the case of bone, it is strongly resistant to it in the case of tooth enamel. Soft tissues such as hair, skin, and flesh may be analyzed on the rare occasions where they are preserved, usually through mummification (intended or naturally occurring through desiccation) or freezing (e.g., permafrost burials). Each tissue represents a different time-slice of an individual's diet, depending on growth period and turnover rate: bone with its slow turnover integrates long-term diet, while hair provides a linear record of short- to medium-term diet, and teeth record a snapshot of childhood diet consumed during their short formation.

**Figure 1** Diagram to show correlation between carbon and nitrogen isotopic values of collagen from archaeological humans (●), and their expected food sources. Human populations are: 1, Neanderthals; 2, British Neolithic farmers; 3, Native American marine mammal hunters; 4, British Mesolithic hunter-fishers. (Data replotted from: Richards *et al.* (2000) *Proceedings of the National Academy of Sciences of the United States of America* 97: 7663–7666; Richards and Hedges (1999) *Journal of Archaeological Science* 26: 717–722.)

Samples are analyzed by either dual inlet isotope ratio MS, or more commonly nowadays by continuous flow isotope ratio MS. The development of the latter technique has greatly increased the number of palaeodietary studies through the reduced analysis time and the resulting greater number of analyses performed.

An individual's carbon isotope signal indicates the plant types at the base of their ecosystem. When atmospheric carbon dioxide is incorporated through photosynthesis into plants, the heavier isotope is discriminated against, resulting in plants being depleted in  $^{13}\text{C}$  relative to the atmosphere. Most plants photosynthesize using the Calvin–Benson or  $\text{C}_3$  pathway, and such plants typically have  $\delta^{13}\text{C}$  values of  $-27\text{‰}$  compared to atmospheric  $\text{CO}_2$  at  $-8\text{‰}$ . A smaller group of plants use the Hatch–Slack or  $\text{C}_4$  pathway, which results in less discrimination against  $^{13}\text{C}$ , producing plants with  $\delta^{13}\text{C}$  of typically  $-11\text{‰}$ .  $\text{C}_4$  plants are adapted to hot, dry environments, and include the important human food crops of maize, millet, sorghum, and sugar cane, as well as tropical savannah grasses and sedges. The  $\delta^{13}\text{C}$  signature is passed almost unchanged up the food chain, allowing the differentiation of  $\text{C}_3$  consumers from those that eat  $\text{C}_4$ , either directly (eating plants) or indirectly (eating herbivorous animals).

The timing of the introduction of maize agriculture to eastern North America was revealed through a

combination of radiocarbon dating and carbon isotopic analysis: human bone collagen  $\delta^{13}\text{C}$  values indicated a dramatic shift from a  $\text{C}_3$ -based diet, typical of hunter-gatherers, to one rich in  $\text{C}_4$  plants such as maize at around AD 1000, much later than had been predicted.

Hair samples from Nubian burials excavated in modern-day Sudan allow us a glimpse of the agricultural year 2000 years ago: carbon isotopic analyses along each hair strand show a shift from a  $\text{C}_3$  to  $\text{C}_4$  signal within a matter of months, echoing the modern practice of alternating winter  $\text{C}_3$  and summer  $\text{C}_4$  crops in this harsh environment.

Further back in time, carbon isotopes have provided clues as to the diet of early hominids in Africa. Analyses of the tooth enamel of *Australopithecus robustus* from Swartkrans produced a surprising  $\text{C}_4$  signal, as *A. robustus* was assumed to have a  $\text{C}_3$  vegetarian diet of fruits and nuts. Since dental morphology and microwear do not indicate direct grass consumption, *A. robustus* must have incorporated a  $\text{C}_4$  signal either directly by eating  $\text{C}_4$  sedges and their tubers, or indirectly by consuming animals living in the  $\text{C}_4$  savannah grassland environment. But both of these suggest that *A. robustus* utilized a wider range of resources than previously thought.

Marine environments are enriched in  $^{13}\text{C}$  relative to  $\text{C}_3$  terrestrial ecosystems, due to the thermodynamic isotope fractionation in the dissolution of  $\text{CO}_2$  at the ocean/atmosphere interface, and this difference allows us to distinguish whether humans were eating marine or terrestrial foods. In northwest Europe, the transition from hunting, gathering, and fishing in Mesolithic period to horticulture and pastoralism in the Neolithic is indicated by a shift in human bone collagen  $\delta^{13}\text{C}$  values, from those indicating marine resource consumption (ca.  $-14\text{‰}$  to  $-12\text{‰}$ ) to those showing a dependence on terrestrial plants and animals (around  $-19\text{‰}$  to  $-23\text{‰}$ ).

Nitrogen is incorporated from atmospheric  $\text{N}_2$  in the soil into plants. Little isotopic fractionation occurs during this process, but at subsequent steps in the food chain (plant to herbivore, herbivore to carnivore, etc.) there is an observed enrichment in  $^{15}\text{N}$ , resulting in an  $\sim 3\text{--}5\text{‰}$  increase in  $\delta^{15}\text{N}$  with each trophic level. Measurement of  $\delta^{15}\text{N}$  therefore allows an assessment of an individual's position in the food chain, and therefore in humans, an indication of how much animal protein is consumed (either as meat or as secondary products such as milk and cheese). Neanderthal specimens from Belgium and Croatia have been found to have  $\delta^{15}\text{N}$  similar to contemporary large carnivores such as wolf, hyena, and cave lion, providing quantitative support for the belief, based on other archaeological evidence, that

Neanderthals were efficient large-game hunters in Palaeolithic Europe.

Besides answering questions such as what past people ate, and how subsistence changed through time, isotopic analyses can help to investigate differences within populations, related to age, gender, and status. Studies of an Anglo-Saxon population at Berinsfield in Oxfordshire showed that, based on nitrogen isotopic values, poor people seemed to eat more fish than richer individuals (those buried with more grave goods): although initially counterintuitive, as fish is often assumed to be a high-status food, one explanation is the exploitation of free riverine resources by those too poor to own cattle, sheep, or goats.

**Human life histories** By analyzing different skeletal elements, formed at different points in an individual's life, we can gain an insight into diet and residence at various points in life.

The major dietary shift that all humans undergo early in life is the transition from breastfeeding to solid foods, and the timing of this weaning has important demographic connotations. As breastfeeding infants are a trophic level above their mothers, a decrease in infant  $\delta^{15}\text{N}$  values is observed when breast milk is replaced by solid foods, paralleled by a change in  $\delta^{18}\text{O}$  related to the replacement of water derived from breast milk by surface water. A study of teeth from the Guatemalan site of Kaminaljuyú, dating from 700 BC to AD 1500 showed that solid foods were introduced earlier than 2 years of age, but breast milk was a major source of water for at least a further year.

A combination of trace element analyses such as strontium with stable carbon and nitrogen isotope analyses can show whether individuals moved geographically, as well as changing their diet. Isotopes were measured on bones and teeth of the  $\sim 5300$ -year-old Neolithic human mummy preserved in an alpine Glacier in northern Italy in an attempt to reconstruct aspects of his life. Radiogenic Sr, Nd, and Pb isotopes passed into the body from food relate to the local geological environment, and the stable isotopes of O and C provide information about altitude and position relative to the main Alpine watershed. Differences in the  $^{87}\text{Sr}/^{86}\text{Sr}$  of his tooth enamel (formed in early childhood) and bone (probably representing the final decade of life) suggest that as an adult he had moved to a different location from that of his childhood, whilst the  $\delta^{18}\text{O}$  data suggest the Iceman had spent his childhood at lower altitudes than his burial site.

Using a similar methodology but at a larger scale, trace element analyses can be used to look at the movement of people around the landscape. A comparison of strontium isotope analyses of teeth

and bone from a number of individuals from a Bell Beaker population in Germany showed that ~20–25% of the population were incomers to the region in which they were buried, as their teeth and bone  $^{87}\text{Sr}/^{86}\text{Sr}$  were significantly different. Based on the gender distribution, females appeared to be more likely to have moved, suggesting a possible pattern of exogamy.

**Animals** Palaeodietary reconstruction usually focuses on humans, but in certain situations, the study of animal remains can provide information on human activities such as herd management and transhumance. Studies of carbon, oxygen, and strontium isotopes in sheep teeth from Late Stone Age Kasteelberg in Southern Africa indicate that there was little seasonal movement of animals from the coast to inland, suggesting that the transhumance practiced in that region by the historical Khoekhoe peoples developed only later in prehistory, when cattle pastoralism began.

### Residue Analysis

The ability to analyze organic residues in and on archaeological artifacts such as ceramics and stone tools is a result of the development of compound-specific analytical techniques such as gas chromatography (GC), gas chromatography–mass spectrometry (GC–MS), and more recently gas chromatography–combustion–isotope ratio mass spectrometry (GC–C–IRMS). These techniques enable individual compounds, generally lipids, to be chemically characterized from amorphous and often degraded residues left on artifacts by human activities. From such ‘biomarker’ molecules, the original material can then be identified. Lipids have been shown to be well preserved when adsorbed within an unglazed ceramic matrix, and a variety of different compounds have been measured including fatty acids, waxes, and sterols of both animal and plant origin. Studies on stone tools have been less successful, due to problems of diagenesis and lack of reproducibility.

Whereas palaeodietary reconstruction using light stable isotope and trace element analysis is generally focused on the consumer, giving an idea of overall diet, analysis of organic remains from the preparing, cooking, and storing of food provides an insight into specific foodstuffs that were consumed. The types of fats and their distribution within pots of different shapes and sizes from the Saxon settlement of Raunds in Northamptonshire showed that form was correlated with function: large shallow dishes had a high density of animal fats on their bases, suggesting they were placed under roasting meats to collect the dripping fat, whereas taller ‘top hat’ jars had the distinctive leaf waxes derived from cabbage leaves

adsorbed around their rims, suggesting that they were vegetable boiling pots.

Pots dating to 6000 BC from the Early Neolithic site of Çatal Höyük in Turkey were found to have contained a mixture of ruminant and pig fats, but no dairy fats, based on GC–C–IRMS analyses of palmitic ( $\text{C}_{16:0}$ ) and stearic ( $\text{C}_{18:0}$ ) fatty acids.

Residue analysis is not limited to the study of food remains, and analysis of nondietary related residues such as waxes, resins, and pitches can give an idea of daily life in prehistory, as well as trade and technology. GC–MS has been used to identify that Apache, Washo, and Paiute peoples in California waterproofed bottles and baskets using pinyon and lac resins. In the Old World, analyses have shown that pine pitches and tars had a wide variety of uses, such as sealing Hellenistic amphorae, repairing Roman jars, and waterproofing ships from pre-Roman times to the Tudor warship ‘Mary Rose’. In Minoan Crete, GC–MS and GC–C–IRMS demonstrated that beeswax was burnt as lamp fuel, whilst in Saxon Britain, lamps were more likely to contain sheep or cow tallow.

### Chronometric Dating

Assessment of an accurate and precise chronology is crucial for resolving many questions in human prehistory, and MS underlies three important dating techniques.

#### Radiocarbon and Other Cosmogenic Isotopes

Radiocarbon provides the most common archaeological dating method, and can be applied back to ~40 ky. Organic remains suitable for dating (e.g., wood, charcoal, bone) are often abundant on archaeological sites. In the past, the  $^{14}\text{C}$  concentration in a sample was determined by counting beta particles emitted when  $^{14}\text{C}$  decays to  $^{14}\text{N}$ . This required a large sample size (1–10 g), and measurement times could be as long as weeks or months. The development of radiocarbon accelerator mass spectrometry (AMS) reduced sample requirements to a few milligrams and measurement times to less than an hour, and has pushed the practical limit of radiocarbon back to beyond 50 ky.

The particular challenge in measuring  $^{14}\text{C}$  by MS stems from its extremely low abundance (1 part in  $10^{12}$ ), in particular relative to  $^{14}\text{N}$  which is isobaric. The problem can be solved using tandem accelerators, where negative ions are produced at the source, accelerated to a stripper where they are converted to positive ions (a transition that excludes most of the  $^{14}\text{N}$ ) for detection. High acceleration voltages (> 1 MeV) ensure molecular interferences are minimal.

The application of accelerators to radiocarbon dating has been deemed a revolution in archaeology. This is partly because of the much larger sample throughput possible, but also because the integrity of the samples can be more closely controlled. For example, a single carbonized seed can be dated, rather than an amalgamation of many tens (which may not be of the same date) required for conventional beta counting. Organic remains from a single growing season (e.g., a seed) are much more representative of the date of a deposit, whereas charcoal may represent wood already several hundreds of years old. The technique is obviously less destructive, allowing AMS to be used in the dating of small samples, including the Turin shroud which was dated to 1260–1390 AD.

Radiocarbon is produced in the upper atmosphere from various interactions with cosmic nucleons, and there are other isotopes produced in similar reactions that are of interest to archaeology. The interaction and spallation of atmospheric nuclei with cosmogenic nucleons generates a flux of high-energy neutrons reaching the earth's surface which can give rise to the *in situ* production of 'cosmogenic isotopes' in materials of archaeological relevance. It has been proposed that the production of stable cosmogenic isotopes such as  $^3\text{He}$  and  $^{21}\text{Ne}$  can be used to calculate the time elapsed since a material was exposed to the neutron flux. If a material has been exposed long enough to produce measurable cosmogenic isotopes, and then reburied to a depth of  $>1.5\text{ m}$ , the unstable cosmogenic isotopes (e.g.,  $^{10}\text{Be}$ ,  $^{26}\text{Al}$ , and  $^{36}\text{Cl}$  with half-lives in the range  $10^5$ – $10^6$  years) may provide chronological information. Production rates for these isotopes are low ( $10$ – $100\text{ atoms g}^{-1}\text{ year}^{-1}$ ), however, requiring lengthy chemical purification and the use of AMS for measurement. To date, archaeological applications have been few, largely giving maximum exposure dates for stone, and by implication maximum dates for human activity such as rock painting or construction of monuments.

### Uranium-Series Dating

Uranium-238 and Uranium-235 are the parent isotopes of decay chains that can be used to provide a chronology back to  $\sim 500\text{ ky}$ . In an old system ( $>500\text{ ky}$ ) a radioactive secular equilibrium is established between the parent  $^{238}\text{U}$  or  $^{235}\text{U}$  and their daughter radioisotopes. Natural processes can disrupt this equilibrium, and the subsequent in-growth of the long-lived daughter isotopes, as equilibrium is re-established, provides the chronological information.

Of particular interest to archaeology are the long-lived daughters of  $^{238}\text{U}$  ( $^{234}\text{U}$  and  $^{230}\text{Th}$ , with half-lives of 245 and 75.7 ky, respectively) and the long-lived  $^{231}\text{Pa}$  daughter (with a half-life of 32.7 ky)

of  $^{235}\text{U}$ . Uranium is relatively soluble, so in aqueous systems, the parent uranium isotopes are separated from their insoluble  $^{230}\text{Th}$  and  $^{231}\text{Pa}$  daughters. Hence, materials such as calcium carbonate precipitates (e.g., stalagmites or flowstones in caves) will initially contain no daughter isotopes. The daughters in-grow at a rate defined by their half-life, and the measurement of  $^{230}\text{Th}/^{238}\text{U}$  and  $^{231}\text{Pa}/^{235}\text{U}$  can be used to calculate the time since precipitation of the material. An additional complication for the  $^{238}\text{U}$  decay series is that  $^{234}\text{U}$ , intermediate to  $^{238}\text{U}$  and  $^{230}\text{Th}$ , is fractionated by geochemical processes, and is rarely in secular equilibrium with  $^{238}\text{U}$ . Hence, both  $^{234}\text{U}/^{238}\text{U}$  and  $^{230}\text{Th}/^{238}\text{U}$  are required to calculate a date.

Conventionally, alpha spectrometry was used to determine the isotopic ratios, but more recently thermal ionization and plasma mass spectrometric methods have been employed, greatly increasing precision, decreasing sample size requirements, and pushing back the older limit of datable samples.

An additional requirement of the method is that the sample remains a 'closed system', that is, there is no further input or loss of uranium after initial formation of the sample. Generally, calcium carbonate deposits remain a closed system and provide the most accurate uranium-series chronologies. However, dating carbonate deposits only indirectly dates the archaeology. In the best scenario, cultural horizons will be interstratified by flowstones or stalagmites. This is the case for some of the Neanderthal bearing layers at the cave site of La Chaise de Vouthon in France, which are sandwiched between flowstones, allowing a date to be measured to between 98 and 122 ky. Where just a single flowstone layer is present, only a minimum or maximum age can be given for the archaeological horizons above or below it, but these ages are still invaluable. Minimum dates of 400 and 510 ky for *Homo erectus* fossils from Zhoukoudian and Nanjing demonstrated a significant gap between the last *H. erectus* and the earliest *H. sapiens*, forcing a re-evaluation of the view that they may have been contemporary in this region.

The co-occurrence of archaeological deposits with datable calcite is unfortunately rare, and because of this, attempts have been made to date more controversial materials (e.g., bones and teeth). Bones and teeth present particular problems for uranium-series dating because they remain open systems. Uranium is taken up from the burial environment, and can also be lost, and a model of this migration is required to calculate a date from the measured isotope ratios. One approach utilizes a model of the diffusion of uranium into a bone that predicts specific distributions of uranium and uranium-series isotopes across

a bone section under particular geochemical conditions. Measurement of these distributions has recently been facilitated by the development of laser ablation plasma mass spectrometry. The distributions are compared with those predicted by the model, and where there is good agreement a uranium-series date can be calculated. The use of laser ablation also has the advantage of being virtually nondestructive (the laser spot size can be as small as 5  $\mu\text{m}$ ), which allows dating of the most valuable fossil specimens.

### Potassium–Argon Dating

Potassium-40 decays to  $^{40}\text{Ar}$  with a half-life of 1250 My. Extreme heating events such as volcanic eruption will drive off the gaseous  $^{40}\text{Ar}$ , allowing use of the  $^{40}\text{K}/^{40}\text{Ar}$  ratio to determine the time elapsed since the heating. In the traditional approach, the potassium content of a sample was measured using techniques such as atomic absorption spectrometry, and the  $^{40}\text{Ar}$  in a high-resolution gas source mass spectrometer. Greater precision, however, can be achieved by irradiating the sample in a neutron flux to convert some of the K to  $^{39}\text{Ar}$  and measuring  $^{40}\text{Ar}/^{39}\text{Ar}$  in the mass spectrometer. Single grains of potassium-rich minerals can be heated with a laser to release the argon allowing detection of older contaminating grains.

Archaeological applications of K–Ar dating require volcanic material to be associated with cultural layers. K–Ar on tuffs within Bed I at the Olduvai Gorge in Tanzania provided a date of  $\sim 1.8$  My for *Homo habilis*, and was also used to calibrate the Olduvai magnetic event. New archaeological applications are being developed with the increasing sensitivity of the technique, which enables younger samples to be dated. For example,  $^{40}\text{Ar}/^{39}\text{Ar}$  was used to date anatomically modern *Homo sapiens* fossils from Herto in Ethiopia to between 154 and 160 ky. According to current morphological classification, these fossils represent the earliest known examples of modern humans.

### Introduction

Mass spectrometry (MS) is a powerful tool for the structure characterization of small amounts of

material. Its high sensitivity and rapid response make it ideal for the analysis of trace components obtained from biofluids and tissues, especially when it is combined with a chromatographic separation. Since the 1990s, advances in technology have resulted in the availability of cheaper systems that have the potential to revolutionize the application of MS in clinical analysis. Also, the advance of powerful software

tools to help in the analysis of the large quantities of data produced during a mass spectrometric analysis, with a high level of automation, has made MS more available as a routine analytical tool. It has given rise to new areas of research, especially the so-called proteomics and metabonomics.

Nonroutine use of MS in clinical analysis covers a large number of applications involving the analysis of all kinds of biofluids and tissues for analytes ranging in mass from expired gases to proteins. The emphasis in this article will be on the use of MS in drug metabolism and pharmacokinetic studies, the identification and quantification of endogenous components in both normal and diseased states, and the increasing use of MS in the analysis of biopolymers. Although these techniques have been available for many years the introduction of new technology will make them less costly and easier to apply, and this will be indicated throughout this article.

## Sample Types

All kinds of clinical samples can be analyzed using MS combined with suitable extraction and cleanup procedures. Noninvasive samples include expired air, urine, feces, milk, saliva, and sweat. Invasive procedures yielding samples of blood, bile, cerebrospinal fluid, amniotic fluid, and tissue samples of many types are also used to provide material for mass spectrometric analysis. Samples can be analyzed for endogenous components, for instance, profiling disease types, or for exogenous components and metabolites, for instance, drug metabolism studies. The recent development of high-mass MS combined with powerful information systems, driven by the needs of biomedical research, has brought the analysis of peptides, proteins, and other biopolymers within reach and also allowing investigation of abnormal proteins. The examination of total protein contents of various cell types is undertaken. This technique is called 'proteomics' and will have application in clinical analysis.

## Sample Preparation

The direct analysis of some samples is now possible. Breath analysis has always been a direct technique but the direct analysis of other biological samples such as urine and bile has required the development of new methods for handling such samples. Hence, direct analysis of urine using liquid chromatography-mass spectrometry/mass spectrometry (LC-MS/MS) procedures is often used in metabolism studies with

either electrospray ionization (ESI) or atmospheric pressure chemical ionization (APCI) sources providing the ionization mechanism. Direct analysis of bile has been described with the use of fast atom bombardment-MS (FAB-MS) for the analysis of bile acids, but FAB-MS has been largely superseded by either ESI- or APCI-MS. The same analysis of bile acids can be carried out with more ease using negative-ion APCI.

Most other relatively low molecular mass analytes, such as steroids, fatty acids, require separation and often derivatization prior to analysis. Various steps that may be used in sample preparation are shown in **Table 1**. This is not meant to be an exhaustive list and many references in the primary literature use specific extraction and derivatizing agents.

Care always has to be taken with sample cleanup because of the complexity of biological matrices. Almost all biological samples contain sodium chloride and this can severely disrupt FAB, ESI, or APCI analyses, for instance. Even if salt is removed by the use of appropriate absorption columns, impurities may be introduced at this stage from poor-quality solvents and absorbents. Thin layer chromatography (TLC) is often used as a separation technique but most commercial plates yield extracts containing a

**Table 1** Examples of the various stages in the extraction and analysis of body fluids and/or tissues by MS

Stage	Procedure
Pretreatment	Blood: centrifuge to yield plasma Tissue: solubilize Tissue: homogenize
Extraction	Solvent partition Solid phase, e.g., Lipidex, etc. Immunoabsorption
Fractionation	Dialysis to remove inorganic salts Chromatography (LC, TLC, column, gel) Ion-exchange chromatography
Derivatization	Ketones: oximes Hydroxyl groups: trimethylsilyl or <i>t</i> -butyldimethylsilyl ethers Carboxylic acids: methyl esters
Chromatography-mass spectrometry	Amines: trifluoroacetates Capillary GLC with EI, CI-MS LC: with thermospray, FAB-MS, ESI-MS, APCI-MS SFC (supercritical fluid chromatography)-EI, CI-MS Capillary electrophoresis and related techniques – nanoflow ESI
Accurate mass measurement systems for use with GLC or LC	Sector instruments Ion cyclotron resonance analyzers Orthogonal time-of-flight analyzers (preferred), single analyzers, and in hybrid systems such as QqT

range of binders, modifiers, etc.; again this is detrimental to most ionization techniques. The act of derivatization also introduces impurities due to partial reactions, formation of by-products, and introduction of other impurities. Indeed, in many steroid analyses relying on a final gas chromatographic-mass spectrometric (GC-MS) analysis of a trimethylsilyl ether/oxime, the act of derivatization introduces so many impurities that additional clean-up is often used before the final GC-MS step.

## Types of Analyte

The types of analyte can vary from expired gases to high relative molecular mass proteins but considerable differences in the type of mass spectrometer used for such analyses means that no single instrument will cover the whole range. **Table 2** lists some typical analytes and the kind of mass spectrometric analyses that would be used to characterize them.

## Applications

### Isotope Ratio Mass Spectrometry

Stable isotopes and isotope ratio mass spectrometry are used extensively in nutritional and metabolic research, especially in pediatric research. For example, in an experiment to determine the glucose oxidation rate, the patient swallows an aqueous solution of glucose. The earliest workers used naturally enriched  $^{13}\text{C}$ -glucose obtained from maize sugar, but more recently the availability of synthetic  $^{13}\text{C}$ -glucose with up to 98% atom enrichment has gained favor. The administered glucose is assumed to enter a single plasma pool from where it is either oxidized to  $\text{CO}_2$ , stored as glycogen or fat, or the carbon enters various body cycles including production of protein. At steady state the amount of enrichment of  $^{13}\text{C}$  in both plasma glucose and in expired air remains constant. Since the amount of glucose entering the

pool is known, the glucose oxidation rate can be determined.

Similar studies are conducted using  $^{13}\text{C}$ -enriched triglycerides to study fatty acid metabolism, again following the expiration of  $^{13}\text{CO}_2$ . Protein turnover has been studied by administering  $^{15}\text{N}$ -enriched amino acids and measuring enrichment in excreted urea.  $^{13}\text{C}$ -leucine has also been used but on this occasion  $^{13}\text{CO}_2$  enrichment in expired air was followed.

In all experiments the mass spectral analysis remains similar. Very small amounts of  $^{13}\text{C}$  are measured, requiring high precision abundance measurements. Classically, the instruments have used fixed detectors for  $m/z$  44 ( $^{12}\text{C}^{16}\text{O}_2$ ),  $m/z$  45 ( $^{13}\text{C}^{16}\text{O}_2$  and  $^{12}\text{C}^{16}\text{O}^{17}\text{O}$ ), and  $m/z$  46 ( $^{12}\text{C}^{16}\text{O}^{18}\text{O}$ ). A standard  $\text{CO}_2$  sample is used to calibrate the detector responses and the analyte is introduced by a batch inlet process. The correction at  $m/z$  45 for  $^{17}\text{O}$  is made from the amount of  $^{18}\text{O}$  present at  $m/z$  46 by assuming that the  $^{17}\text{O}/^{18}\text{O}$  ratio remains constant.

More recently continuous-flow devices have been introduced using a combustion chamber to oxidize the carbon to  $\text{CO}_2$ , followed by scrubbers to remove water and oxygen. This is equivalent to interfacing an automated CHN analyzer to the mass spectrometer. Such devices can be used to oxidize carbon-containing compounds separated by GC, for instance. Measurements of naturally expired  $\text{CO}_2$  can also be made using such apparatus. They do not require combustion and enter the system after the combustion chamber but pass through the scrubbers. This system is usually automated.

A number of disease states and physiological processes have been studied using these techniques; a representative selection is shown in **Table 3**.

### Endogenous Components – Identification

The introduction of GC-MS in the 1960s revolutionized the analysis for endogenous components in blood and urine. Indeed, one of the earliest uses of GC-MS was the analysis of steroid conjugates in

**Table 2** Typical analytes derived from biological systems and analytical methods used

Analyte	Example	Mass spectrometry
Gases	Carbon dioxide, anesthetics	Gas analyzer Isotope ratio MS
Low relative molecular mass (100–600)	Steroids, fatty acids	GC-MS, LC-MS
Polar materials (200–2000)	Sugars, nucleosides, small peptides	LC-MS, FAB-MS
Drugs and metabolites	Glucuronides, sulfates	LC-MS/MS, FAB-MS/MS
Peptides, proteins	Endorphins, albumin, proteomics	Digest followed by LC-ESI-MS/MS, nanoflow-MS/MS, MALDI-ToF-MS

GC-MS, gas chromatography-mass spectrometry; LC-MS, liquid chromatography-mass spectrometry; FAB-MS, fast atom bombardment-mass spectrometry; MS/MS, tandem mass spectrometry; ESI-MS, electrospray ionization-mass spectrometry; MALDI-ToF-MS, matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry.

**Table 3** Some physiological processes and disease states studied by isotope ratio mass spectrometry

Study	Administered substrate	Analysis
Glucose oxidation	Natural $^{13}\text{C}$ glucose	Expired $^{13}\text{CO}_2$
Fatty acid metabolism	L- $^{13}\text{C}$ trioctanoate	Expired $^{13}\text{CO}_2$
Protein metabolism	$^{15}\text{N}$ -glycine	$^{15}\text{NH}_3$ , $^{15}\text{N}$ -urea
Amino acid metabolism	$^{13}\text{C}$ -leucine	Expired and plasma $^{13}\text{CO}_2$
Amino acid metabolism	$^2\text{H}_5$ -phenylalanine	Urine/plasma phenylalanine and tyrosine
<i>Campylobacter pylori</i>	$^{13}\text{C}$ -urea	Expired $^{13}\text{CO}_2$
Hypoglycemia	$^{13}\text{C}$ -glucose, $^2\text{H}_2$ -glucose	Plasma glucose
Zellweger's syndrome	$^{13}\text{C}$ -phytanic acid (PA)	Plasma PA and HO-PA
Maple syrup urine disease	$^2\text{H}_5$ -Phenylalanine	Urine/plasma phenylalanine and tyrosine

blood by Sjövall and co-workers. Since that time the mass spectrometric determination of steroids and other small molecules has continued as a research tool but, probably due to the cost and complexity of the assays, has not become a universally accepted routine clinical diagnostic aid.

The isolation and analysis of steroids from biofluids requires an extraction step, followed by purification and derivatization. Extraction is commonly carried out by passing the biofluid through a solid-phase absorbent, usually a C18 cartridge. Up to 50 ml of urine can be passed through the cartridge. After washing with water, steroids are recovered by elution with methanol. Plasma is treated with solvent to precipitate protein (Shackleton, for example, uses acetone-ethanol 1:1 (v/v) and adds 1–2 ml plasma to 20 ml solvent in a sonic bath). After 10 min the solution is cooled and centrifuged. The pellet is resuspended in further solvent and extracted again. The combined extract is evaporated to dryness and chromatographed to separate conjugated and free steroids using an ion-exchange resin. The conjugated fraction is hydrolyzed using  $\beta$ -glucuronidase (*H. Pomatia*) and then cleaned up again using a second C18 cartridge separation.

Prior to GC-MS analysis, the steroid fractions require derivatization. Ketosteroids are usually converted to oximes using methoxylamine, benzylamine, or hydroxylamine hydrochloride in pyridine. Two epimers of the oxime are formed (*E* and *Z*). Hydroxyl groups are then derivatized as trimethylsilyl (TMS) ethers. After formation of the TMS derivative, the extract is further purified by chromatography on a small column of Lipidex<sup>TM</sup> 5000. An alternative to TMS is the use of *t*-butyldimethylsilyl (*t*-BDMS) ethers, but although conferring desirable mass spectrometric properties, namely an intense  $M - 57$  ion, the *t*-BDMS group is 42 U heavier than TMS and the formation of poly *t*-BDMS ethers may increase the relative molecular mass of the steroid derivative beyond the mass range of small quadrupoles.

GC-MS profiles obtained from individuals with disorders affecting steroid synthesis may be very different from normal (Figure 1). A range of clinical conditions have been identified, many due to congenital defects affecting cortisol synthesis, which may be analyzed using these methods. Some of these have been tabulated by Shackleton and co-workers (Table 4).

Steroids and similar lipids do not ionize well using ESI or APCI and hence GC-MS remains the favored analytical procedure. The introduction of systems combining a gas chromatograph with an orthogonal axis time-of-flight mass spectrometer (oa-ToF/MS) gives better resolution and the ability to use accurate mass measurement. Thus, an extra parameter is introduced into the analysis, namely the components accurate rather than nominal mass, which improves the identification of the analyte. It also gives important extra data used for the structural characterization of unrecognized steroids or other endogenous components.

A number of other endogenous materials can be analyzed using these techniques, i.e., extraction, derivatization, and GC-MS analysis, to provide a clue to a particular error of metabolism based on the presence or absence of certain components. The scope of such analyses is shown in Table 5.

The increasing application of LC to generate chromatographic profiles enables more-polar compounds such as acids to be analyzed without derivatization. Sensitive LC-MS systems have been developed but reported clinical applications are not yet as numerous as GC-MS. Two LC-MS techniques have been widely accepted for MS applications, namely ESI and APCI interfaces. These have almost completely replaced earlier thermospray and 'flow-FAB' interfaces (Table 6).

APCI ionization is one of the most widely used techniques for LC-MS. It relies on the formation of protonated or cationized molecules in positive-ion mode, or on deprotonated or anionized molecules in the negative-ion mode. However, it is by no means a

**Figure 1** GC-MS Profile analysis. Total ion chromatogram profiles produced by scanning methoxy-trimethylsilyl derivatives of urinary steroids. (A) Profile from a patient with 11 $\beta$ -hydroxylase deficiency in which the principal steroids are metabolites of 11 $\beta$ -deoxycortisol (substance S) such as tetrahydrosubstance S (THS) and hexahydrosubstance S epimers (HHS). (B) Profile from the patient's father; this profile is essentially normal. Some of the major metabolites are C<sub>19</sub> steroids such as androsterone (An), etiocholanone (Etio), pregnanetriol (PT), and cortisol metabolites (THE, tetrahydrocortisone; THF, tetrahydrocortisol and 5 $\alpha$ -THF, 5 $\alpha$ -tetrahydrocortisol). Peaks 1–3 are internal standards. (Reprinted from Shackleton CHL, Merdinck J, and Lawson AM (1990) In: McEwan CN and Larsen BS (eds.) *Mass Spectrometry of Biological Materials*, pp. 297–377. New York: Dekker; courtesy of Marcel Dekker Inc.)

**Table 4** Some disorders affecting steroid synthesis and metabolism

<i>Disease</i>	<i>Cause</i>	<i>Change in urinary steroid profile</i>
Congenital adrenal hyperplasia	21-Hydroxylase deficiency	Metabolites of cortisol grossly reduced; 21-deoxysteroids (17-hydroxypregnanolone, pregnanetriol and pregnanetriolone) and androgen metabolites highly elevated
	11 $\beta$ -Hydroxylase deficiency	Metabolites of cortisol greatly reduced; 11-deoxysteroids (e.g., tetrahydrosubstances S) and 11-deoxyandrogens elevated
	3 $\beta$ -Hydroxysteroid dehydrogenase-isomerase defect	Metabolites of cortisol greatly reduced; 3 $\beta$ -hydroxy-5-ene steroid sulfates markedly increased
	17 $\alpha$ -Hydroxylase deficiency	Metabolites of cortisol and androgens greatly reduced. Dominant urinary steroids are metabolites of corticosterone (e.g., tetrahydrocorticosterone and 5 $\alpha$ -tetrahydrocorticosterone)
Mineralocorticoid (or apparent mineralocorticoid) excess syndromes	11-Hydroxysteroid dehydrogenase deficiency (cortisol oxidase deficiency)	Relatively low cortisol metabolite excretion. Tetrahydrocortisone greatly reduced relative to tetrahydrocortisol and 5 $\alpha$ -tetrahydrocortisol
	Adrenal adenoma	High excretion of tetrahydroaldosterone and/or 18-hydroxycortisol
	Dexamethasone-suppressible hyperaldosteronism	High excretion of 18-hydroxycortisol and tetrahydroaldosterone
	Aldosteronism (elevated aldosterone production)	High excretion of tetrahydroaldosterone and 18-hydroxytetrahydroaldosterone
Hypercortisolism	Excess adrenal cortisol secretion (Cushing's disease)	High excretion of all cortisol metabolites
	Cortisone reductase deficiency	Elevated excretion of tetrahydrocortisone, cortolones, and androgen metabolites. Extremely low excretion of tetrahydrocortisol, 5 $\alpha$ -tetrahydrocortisol, and cortols
Adrenal tumors		Various patterns of elevated steroid excretion, e.g., high 3 $\beta$ -hydroxy-5-ene steroid excretion or high 11 $\beta$ -hydroxyandrosterone excretion
Gonadal tumors		Various types, e.g., ovarian with high excretion of pregnanetriol and 17-hydroxypregnanolone or testicular with high excretion of testosterone and metabolites and 3 $\beta$ -hydroxy-5-ene steroids
Low pregnancy estrogen production	Placental sulfatase deficiency	High excretion of 3 $\beta$ -hydroxy-5-ene steroids in pregnancy urine. Low urinary estriol excretion
Deficient androgen production	5 $\alpha$ -Reductase deficiency	Low excretion of 5 $\alpha$ -reduced steroids. Diagnosed by high 5 $\beta$ /5 $\alpha$ urinary metabolite ratios, e.g., tetrahydrocortisol/5 $\alpha$ -tetrahydrocortisol
	17 $\beta$ -Hydroxysteroid dehydrogenase deficiency	High excretion of androsterone and etiocholanolone
	Testicular feminization	High excretion of androsterone and etiocholanolone
Mineralocorticoid deficiency syndrome	Pseudohypoaldosteronism (renal tubules unresponsive to aldosterone)	High tetrahydroaldosterone and 18-hydroxytetrahydroaldosterone
	Hypoaldosteronism (corticosterone $\rightarrow$ aldosterone biosynthetic defect)	Low tetrahydroaldosterone, 5 $\alpha$ -tetrahydrocortisone and 18-hydroxytetrahydroaldosterone excretion

**Table 5** Various endogenous components that can be analyzed by extraction, derivatization, and GC-MS

Type of analyte	Derivatives	Applications
Steroids	Oximes, TMS, <i>t</i> -BDMS ethers	Steroid profiles
Bile acids	Methyl esters, TMS ethers	Liver disease, peroxisomal deficiencies
Fatty acids	Methyl esters, TMS, <i>t</i> -BDMS esters	Phospholipids, triglycerides
Urinary acids	Methyl esters, TMS, <i>t</i> -BDMS esters	Acidurias, diabetes
Ketones	Oximes	Diabetes
Prostaglandins	Methyl esters, oximes, TMS, ethers	Healing processes, pain

**Table 6** Characteristics of LC-MS methods used in biological mass spectrometric analyses

Interface	Liquid flow	Ionization technique	Applications
Thermospray	<2 ml min <sup>-1</sup>	Thermospray or discharge assisted thermospray	Steroid sulfates, bile acids
Atmospheric pressure chemical ionization (APCI)	10–1000 µl min <sup>-1</sup>	APCI, positive or negative ion	Conjugates, peptides, small polar molecules
Electrospray	10–500 µl min <sup>-1</sup>	Electrospray	Conjugates, peptides, proteins
Nano-electrospray	<10 µl min <sup>-1</sup>	Electrospray	Conjugates, peptides, proteins with limited amounts

universal source and thermal degradation can be a considerable problem for sensitive molecules (such as polyhydroxylated steroids, which may lose water). Additionally, although many compounds will ionize under a variety of probe temperature and solvent conditions, some have little tolerance to temperature change and only give a useful signal within a narrow temperature window.

Electrospray appears to be useful especially when dealing with compounds that give poor APCI spectra due to thermal degradation (such as glucuronide conjugates). Meanwhile, electrospray and its derivative, 'nanoflow electrospray', have developed a niche in the analysis of proteins. They are especially useful as an ionization method combined with capillary electrophoresis, and for offline analysis of spots retrieved from chromatographic plates.

LC-MS analyses using ESI or APCI have tended to be used for those compounds that are not amenable to GC-MS, such as intact conjugates (especially sulfates and phosphates) and quaternary ammonium salts (phosphatidylcholines, acetylcholine).

Other LC-MS ionization techniques are available but their utility for clinical research is low. Until the advent of ESI and APCI the most popular LC-MS interface was thermospray. Other techniques used with varying degrees of success included flow-FAB, transporter belts, and particle beam interfaces. These have been almost wholly superseded by ESI and APCI.

All these chromatographic mass spectrometric techniques are time consuming because a separation has to be made before the sample can be ionized. Direct analysis of biological samples by MS without

**Table 7** Deprotonated molecular anions observed for bile acids in FAB-MS and APCI-MS

Mass	Assignment	Example
432	Glycomonohydroxycholates	Glycolithocholic acid
448	Glycodihydroxycholates	Glycodeoxycholic acid
464	Glycotrihydroxycholates	Glycocholic acid
482	Tauromonohydroxycholates	Taurolithocholic acid
498	Taurodihydroxycholates	Taurochenodeoxycholic acid
514	Taurotrihydroxycholate	Taurocholic acid

prior separation is very restricted because of the complexity of the samples but some useful work has been reported using FAB-MS for the analysis of bile acids in urine or bile. After passing the biological fluid through a C18 cartridge to desalt it, spectra are obtained by dissolving the mixture in methanol, and adding to glycerol. Negative ions are generated and a partial spectrum over the mass range 400–600 U will show the major conjugated bile acids (Table 7). The introduction of electrospray and nanoflow electrospray means these analyses can be carried out on small samples using a syringe pump to supply the extract to the electrospray needle. It has been shown that changes in the pattern of bile acids secreted can give indications of peroxisomal dysfunction and other liver disease. Thus, direct analysis can be used as a rapid screen. Samples showing abnormalities can then be more rigorously analyzed using LC-MS or GC-MS.

### Drug Metabolism Studies – Identification

All new chemical entities (NCEs) proposed as pharmaceuticals require extensive testing before they can

be introduced to the clinic. The study of metabolism is a major requirement in order to identify any metabolites that may have pharmacological, toxicological, or other properties affecting the efficacy, safety, and use of the drug. MS has played a unique role in the development of metabolism studies and is an essential tool in the development of any NCE. This is in contrast to the slow acceptance of MS in clinical diagnosis, although much of the technology and methodology is common to both.

Traditionally, the identification of metabolites has relied on extraction of biofluids, derivatization, and either LC-MS or GC-MS analysis of the final sample. However, refinement of the methodology has led to the adoption of isotopic labeling and MS/MS techniques as the current state of the art.

In a typical study the compound is administered with a trace level of radioisotope ( $^{14}\text{C}$  or  $^3\text{H}$  normally) and preferably labeled with a moderate amount of stable isotopes ( $^{13}\text{C}$ ,  $^{15}\text{N}$ ,  $^{18}\text{O}$ ,  $^2\text{H}$ ) to generate a characteristic molecular ion pattern in the mass spectrometer. After collecting biofluids such as plasma, urine, and feces, extraction may be carried out using the radiolabel as a tracer to follow drug-derived material. The extracts, or often the biofluid itself, are subjected to LC separation with radiation, UV, and mass spectrometric detection. This allows any components that contain drug-derived material to be readily identified. Significant ions can be subjected to daughter or precursor ion analysis using MS/MS techniques to confirm the relative molecular mass and often to identify the structure of the metabolite even at very low concentrations.

An example of the use of this approach is the study of a sample of horse urine thought to contain furosemide (frusemide). The LC-UV chromatogram at 254 nm showed no clear evidence for the presence of furosemide compared to a control urine sample. LC-MS gave a total ion chromatogram, which again failed to show a clear chromatogram peak for furosemide. However, selected ion monitoring (SIM) of mass 329 u (the deprotonated molecule from furosemide) showed a peak with the expected retention time for furosemide. The analysis was confirmed by a LC-MS/MS experiment. The peak was shown to give a daughter spectrum similar to that obtained from furosemide.

The combination of stable isotopes and MS gives a powerful tool with extra features for the study of drug metabolism. For example, unlike natural products, most synthetic drugs are racemic mixtures. Administering a racemate with one enantiomer labeled with stable isotopes can show up any enantioselective route of metabolism. It is important to administer a racemic mixture because the

enantiomer may affect the metabolism of its optical twin.

However, care must be taken with stable isotopes. The rates of metabolism, especially of deuterated substrates, can be significantly different from those of the unlabeled substrates and the site of deuteration should be chosen with these 'isotope effects' in mind. A classical study with antipyrine (2,3-dimethyl-1-phenyl-3-pyrazalin-5-one) showed that substitution of the trideuteromethyl group in the 3 position switched the dominant metabolite from 3-dimethyl to 4-hydroxyantipyrine. Far fewer isotope effects are observed with  $^{13}\text{C}$  or  $^{15}\text{N}$  labels and these are to be preferred for *in vivo* work.

The technique of LC-MS/MS is a very powerful tool in drug metabolism studies. Mass shifts in daughter ion peaks can often provide sufficient information to enable the structure of a metabolite to be postulated. Software programs have been developed which allow automated screening of LC-MS data sets for the presence of possible metabolites. These often used simple tables of mass shifts obtained after metabolic modification but powerful computing tools such as principal components analysis (PCA) have enabled any changes in the postdose profile to be detected (see below, metabonomics). The introduction of hybrid spectrometers combining a quadrupole and an oa-ToF/MS enables the accurate mass of the parent compound to be determined, confirming its empirical formula. The protonated or deprotonated molecular ion can then be selected using the quadrupole mass spectrometer, fragmented in the collision cell, and analyzed using the oa-ToF, enabling the accurate masses of any fragment ions to be determined. Once a potential metabolite has been proposed it can be synthesized and confirmation of the structure of the metabolite can be made with authentic material.

## Quantification

### Endogenous Components

The quantification of endogenous components in biofluids, in contrast to the quantification of xenobiotic substances, raises problems as no true blanks of a biofluid can be obtained. However, despite the problems this poses, adequately validated assay procedures have been developed, and used as reference methods for the assessment of simpler more routine methods such as colorimetric or radioimmunoassay.

The use of isotopically labeled steroids as internal standards for the quantification of steroids in biofluids has been refined to a high degree. Four crucial steps in the analysis have been identified, namely

extraction, fractionation, derivatization, and GC-MS. Solvent extraction can be used but the use of immunoabsorbents (i.e., using microcellulose-coupled antisera for specific components) affords a high degree of selectivity as well as extraction. Fractionation of the extract may be required followed by derivatization to produce a derivative having good chromatographic properties as well as a significant ion in the mass spectrum. The use of *t*-butyldimethylsilyl ethers is often favored due to the intensity of the  $M - 57$  ion.

Mass spectrometric detection can be of three types:

1. Early work with quadrupoles used SIM at unit resolution, monitoring perhaps two ions for the analyte and two for the standard. However, the selectivity of the ion is not high and often the chromatograms contained many peaks due to isobaric ions (ions of the same nominal mass but different empirical formula, e.g., CO and C<sub>2</sub>H<sub>4</sub>) derived from other components.

2. Although the use of high resolution causes a reduction in absolute sensitivity of detection, the improved selectivity of the ion monitored often yields a higher signal-to-noise ratio. Thus, the use of high-resolution SIM may improve the overall limit of detection. The recent introduction of orthogonal time-of-flight analyzers has brought the cost of instruments capable of accurate mass measurements down dramatically, and small bench top systems are capable of generating accuracies of 5–10 ppm. These analyzers also have the advantages of faster response than scanning systems, enabling spectra to be obtained on sharp chromatographic peaks of 1–2 s width. Also, as a packet of ions are ejected in an instant from the primary beam for analysis in the ToF, no distortion of spectra are seen due to changing quantities of the analyte as the chromatographic peak passes through the ionization source. Mass chromatograms are selected for quantitation; there is no means for ToF analyzers to monitor single ions. These advantages make the combination of GC with oa-ToF a powerful and affordable new tool for the analysis of biofluid extracts.

3. Finally, the use of linked scan or MS/MS techniques can impart even greater selectivity. In this approach, the use of collisionally activated decomposition of a parent ion to give a suitable daughter ion is monitored. For instance, in a typical MS/MS experiment on *t*-BDMS ethers, the first mass spectrometer MS1 would pass the parent ion whilst MS2 would be set to pass the  $M - 57$  ion. This technique is known as selective reaction monitoring. An example is shown in Figure 2, which shows the analyses of a plasma extract of oestradiol-17 $\beta$  obtained using the

**Figure 2** GC-MS analyses of a plasma extract for oestradiol-17/3, as the bis-tertiarybutyldimethylsilyl ether. (A) Low-resolution (1000) selected ion monitoring of  $m/z$  500. (B) Selected reaction monitoring of  $m/z$  500  $\rightarrow$  443; parent resolution 1000. (C) as (B), parent ion resolution 2500. (D) as (B), parent ion resolution 5000. (Reproduced with permission from Gaskell SJ, Gould VJ, and Leith HM (1986) In: Gaskell SJ (ed.) *Mass Spectrometry in Biomedical Research*, pp. 347–361. Chichester: Wiley; © John Wiley & Sons Ltd.)

three techniques. The introduction of hybrid quadrupole–oa-ToF mass spectrometers means a modern more affordable spectrometer can also be used for this type of analysis.

### Toxicity Studies

The study of the ‘metabolome’; i.e., the total mixture of low molecular weight materials present within a

cell, has followed from the development of proteomics (see below). It has application in natural products research to identify active components and in pharmacognosy. It is also used in a semiquantitative manner to identify any compounds that have increased or decreased in concentration following ingestion of xenobiotic substances or in disease states. A particular approach concerning toxicity studies has been termed 'metabonomics'. The definition of metabonomics given by Nicholson is "the quantitative measurement of time related multiparametric responses of multicellular systems to pathophysiological stimuli."

Studying the downregulation or upregulation of these small molecules can provide markers for clinical diagnosis, which can be developed to provide clinical tests. The identification of these markers can be carried out by a combination of LC-MS(/MS) analyses followed by a detailed statistical review of the data sets using, for example, PCA.

Thus, following a normal toxicity study using increasing doses of a xenobiotic substance to elicit a toxic response, biological samples are collected at various time intervals after dosage. After minimal sample preparation LC/MS analyses are carried out leading to large, complex data files. The individual scans from these files are combined into a single scan file. This file is divided into intensity and mass data. The file is sometimes reduced further by grouping the mass data into bins covering 3 or 5 Da ranges. These data are then subjected to PCA. The scores plots are compared between samples and controls and used to identify those mass bins that have increased or decreased in relative concentration compared with the control. This information can be used to construct mass chromatograms using the original LC/MS data files and highlight the components that have changed in concentration. Sometimes it is possible to identify the required component from its simple MS spectrum, but chemical noise is often too great to obtain a clean interpretable spectrum. In these cases product ion spectra are used. An example is the analysis of urine after a toxic insult. PCA analysis indicated that the bin  $m/z$  113–115 was enhanced. Mass chromatography indicated a component giving an ion  $m/z$  114, which was identified as creatinine. An increase in creatinine is expected from liver toxicity. In addition, an increase in a nicotinic acid analog was also reported.

Apart from its use in toxicity studies, this approach (i.e., MS analysis followed by statistical processing of the data set followed by reanalysis of the sample to confirm the identity of perturbed metabolites) has obvious applications in clinical diagnosis following infection or some genetic abnormality.

To meet this demand most instrument companies are now offering automated systems that carry out the analysis and perform PCA processing with minimal intervention.

### Drug Metabolism Studies

The measurement of the concentration of drug-derived materials in biofluids, especially blood (plasma) and urine, is essential for the pharmacokinetic study of the rates of absorption, distribution, metabolism, and excretion. These are known as ADME studies. All such analyses are based on the addition of a known amount of an internal standard to an aliquot of the biofluid, followed by coextraction of the standard and the analyte after a period of equilibrium. The extract is purified and normally a chromatographic separation is carried out prior to detection.

Such assays are closely monitored for both accuracy and precision. Calibration graphs are prepared by adding known amounts of analyte to blank samples of the biofluid under study and extracting these. A plot of the ratio of the response of the analyte to the response of the standard against concentration normally yields a straight line. The equation of this line can be used to calculate the concentration of analyte in unknown samples. These unknown samples should also include reference samples of analyte in biofluid where the concentration of the analyte is known to a quality assurance monitor but not to the analyst. These steps are necessary to ensure the accuracy of the results of the unknown.

These procedures often involve many samples, most of which will be analyzed in duplicate. This in turn has led to the development of automated systems for carrying out these analyses and interpreting the data.

The mass spectrometer's unique ability to differentiate between isotopes has led to the development of the 'stable isotope dilution' method for quantification. Although close analogs and homologs, or even isomers, of analytes are often used as internal standards, problems can arise because the physicochemical properties are not identical for the standard and the analyte. However, careful selection of a stable isotopically labeled analog can give an internal standard that has almost identical chemical properties. Use of such standards can lead to an improvement in both accuracy and precision, but especially precision.

The use of stable isotopes can be extended one stage further. Formulation pharmacists are interested in the amount of drug that is absorbed after oral administration of a tablet, capsule, or liquid

preparation. Experiments to determine this parameter (termed the 'absolute bioavailability') usually involve comparing the areas under the plasma curve after intravenous and oral administration of the compound. However, such studies require a 'wash-out' period between one administration and the other during which time the ADME profile may alter. Examples of this effect include drugs whose rate of excretion is critically dependent on urinary pH. These effects can be nullified by administering the intravenous dose and the oral dose at the same time. Obviously, one would not be able to distinguish between drugs from either route, except by labeling with stable isotopes. An example is shown in Figure 3 when disopyramide phosphate was administered to

**Figure 3** The plasma concentration versus time curves for disopyramide (●) and [<sup>13</sup>C, <sup>15</sup>N]-disopyramide (○) after coadministration of disopyramide phosphate (5 mg kg<sup>-1</sup>) intravenously (i.v.) and [<sup>13</sup>C, <sup>15</sup>N]-disopyramide phosphate (5 mg kg<sup>-1</sup>) by mouth (p.o.) to the rat. Data are the averages from nine animals. The areas under the curves were determined as 3522 ng h<sup>-1</sup> ml<sup>-1</sup> after i.v. and 1381 ng h<sup>-1</sup> ml<sup>-1</sup> after p.o. administration. This gave an absolute bioavailability figure of about 39%. (From Haskins NJ and Waddell KA (1981) Unpublished results.)

rats as an intravenous bolus (5 mg kg<sup>-1</sup>) and its <sup>13</sup>C, <sup>15</sup>N-labeled isotopomer was administered as an oral solution, also 5 mg kg<sup>-1</sup>. This is a versatile technique and can be extended to a range of studies when chemically identical materials are being compared. Thus, studies of various formulations against an orally administered reference solution, of enantioselective metabolism after labeling one enantiomer with label, and establishing kinetics of a single dose during the course of a chronic dosing schedule can all be carried out using a stable isotopically labeled drug.

## Peptides and Proteins

The biggest development in MS in the 1980s to the 1990s has been the introduction of methods for the analysis of larger peptides and proteins. In this context, the development of FAB ionization in the 1980s led to the use of mass spectrometers to determine the primary sequence of peptides, usually following enzymatic digestion. The later developments in the 1990s of matrix-assisted laser desorption/ionization (MALDI)-time-of-flight and ESI-MS allow the analysis of intact peptides and proteins. These developments led to the award of the Nobel Prize for chemistry to Professors Takeda and Fenn in 2002.

Since the 1990s the concentration of technological research on the analysis of large biomolecules has led to the development of a range of methods employing different ionization techniques and mass analysers. The most significant of these have been the combination of MALDI sources with high-performance mass analyzers (oa-ToF and FT-ICR/MS) improving the mass resolution of the spectra; the miniaturization of LC and electrospray systems to enable LC/MS analyses on small amounts of material; and the advent of static or very low flow electrospray using flows of 20 nl min<sup>-1</sup> (the so-called nanoflow electrospray). The attributes and application of these techniques are summarized in Table 8.

The advantage of MALDI-ToF is its mass range, but this is outweighed by its lack of resolution. ESI is technically more difficult because multiply charged ions are observed, but has the advantages of high

**Table 8** Typical parameters for the techniques available for the mass measurement of peptides and proteins

<i>Ionization technique</i>	<i>FAB</i>	<i>MALDI-ToF</i>	<i>Electrospray</i>	<i>Nanoflow electrospray</i>
Mass range	<20 kDa	<500 kDa	<200 kDa	<200 kDa
Mass accuracy	±0.001%	±0.01%	±0.001%	±0.001%
Sensitivity	nmol	<pmol	pmol	<fmol
Sample introduction	Solution in matrix	Dried in matrix	Solution	Solution

FAB, Fast atom bombardment; MALDI-ToF, matrix-assisted laser desorption/ionization time-of-flight.

mass range and good resolution. Examples of the clinical applications of these techniques include the use of ESI-MS to identify sickle-cell hemoglobin from adults and neonates, clearly showing the multi-charged species for the sickle  $\beta$ -chain ( $M_r$  15 837) separated from the normal  $\beta$ -chain ( $M_r$  15 867). Spectra of hemoglobins have also been obtained with MALDI-ToF.

The second technological innovation has been the introduction of powerful computing techniques. PCA of complex data sets has been used to detect up- or downregulation of proteins in complex mixtures in a similar manner to small molecules (see metabolomics above). In addition, application of information technology has revolutionized the rapid identification of peptides and proteins. This has led to MS becoming the method of choice for the study of proteomics.

## Proteomics

Proteomics is the study of the total protein complement of the cell and has obvious applications in clinical diagnosis and research. Once a protein has been recognized as either up- or downregulated it is necessary to try and identify it. Two techniques are being routinely used for this. Firstly separation of the protein mixture using 2D gel plates and a combination of electrophoretic and chromatographic separations. Spots that are changed in intensity can be excised and the protein recovered. After digestion the peptide mixtures can be analyzed by direct analysis using MALDI-ToF or nanoflow ESI. The mixture of peptides can be compared with a library and identification often made. Failing this, peptides can be subjected to MS/MS analysis and a sequence obtained. Again the sequence can be compared with libraries.

The second technique is to digest the total protein mixture and analyze the peptide mixture using LC-MS(/MS) and PCA analysis. After identifying peptides that have been up- or downregulated, comparison with libraries can usually give a positive identification.

A more recent separation technique uses the so-called 'isotope coded affinity tags' (ICAT<sup>TM</sup> Applied Biosystems, Foster City, CA). In this technique, a tag comprising a stable isotopically labeled marker and a biotin molecule is reacted with the protein extract from a perturbed sample whilst an unlabelled tag is used to mark proteins from a control sample. Following purification on an affinity column to isolate the biotin labeled peptides the biotin is cleaved leaving a mixture of tagged peptides. These either have a labeled (clinical sample) or unlabelled marker (control). The mixture is subject to LC-MS(/MS)

analysis. The ratio of label/unlabelled material should be constant if no perturbation has occurred. Differences in relative concentration between the sample and its control will identify target proteins. Sequence data from MS/MS analysis in combination with a library search should identify the protein. Once again commercial systems with a high degree of automation are being developed.

The identification of changes in protein concentration can give crucial information concerning the effect of disease, genetic problems, or exposure to xenobiotic substances (drugs, toxins, etc.). It is becoming a powerful clinical diagnostic tool and again instrument manufacturers are producing automated systems that can carry out the full analysis with minimal operator intervention. This is probably the area of application of MS in clinical research that will see the greatest advance in the next decade.

### Introduction

The analysis of pollutants in environmental samples is complicated by the fact that these compounds are often part of a very complex mixture of hundreds of chemicals and that they are present at extremely low concentrations. Thus, any instrumental technique that is to be used successfully in environmental analysis should allow the separation of such complex mixtures and the identification of the constituents at trace level. Mass spectrometry (MS) is particularly suited for this purpose as it can be coupled with the most important instrumental separation techniques – gas chromatography (GC) and liquid chromatography (LC) – while at the same time it is one of the most sensitive instrumental methods available for the analysis of contaminants. Moreover, it is not only the sensitivity, but also the specificity that makes MS the most powerful instrumental method in environmental analysis.

During the last 10 years the environmental analysis field has changed significantly. Impressive improvements in detection limits are such that parts-per-trillion (ppt) detection is routine for many organic analytes, and detection of a few hundred femtograms of some analytes is now possible, although such detection levels cannot yet be considered routine. Moreover, technologies that have significantly advanced in the last few years include tandem (MS–MS) systems, time-of-flight MS (TOF–MS) and quadrupole-time-of-flight MS (Q–TOF–MS). This article attempts to survey current state-of-the-art in the application of modern mass spectrometric techniques in the environmental analysis.

### Target Compounds

A wide range of man-made chemicals designed for use in industry, agriculture, and consumer goods and

chemicals unintentionally formed or produced as by-products of industrial processes or combustion are potentially of environmental concern. Beside recognized pollutants, numerous new chemicals are synthesized each year and released into the environments with unforeseen consequences. Over the past few decades, analytes having acute toxic or carcinogenic effects and that are persistent in the environment as a result of anthropogenic activity have been widely studied. Examples of these compounds include BTEX (benzene, toluene, and xylene), DDT and its metabolites, polycyclic aromatic hydrocarbons (PAHs), and chlorinated biphenyls (PCBs). While toxic, carcinogenic, and persistent compounds will always be of concern, the last several years have brought an increased interest in endocrine disrupting (ED) compounds – those that interrupt normal hormone function and cause adverse biological effects. ED chemicals encompass a large range of organic, metallic, and organometallic substances (Table 1). There are two classes of substances that can cause endocrine disruption: natural substances (hormone found naturally in the body of humans and animals, and phytoestrogens, substances contained in some plants) and man-made substances. The group of man-made substances comprises synthetically produced hormones designed intentionally to interfere with the endocrine system (e.g., oral contraceptives) and man-made chemicals designed for use in industry, agriculture, and consumer goods that may have unforeseen adverse or synergistic effects. Man-made chemicals also include chemicals unintentionally formed or produced as a by-product of industrial processes or combustion.

Other compounds of interest are the so-called 'emerging contaminants' (Table 1). Emerging contaminants are unregulated contaminants, which may be candidates for future regulation depending on research on their potential health effects and monitoring data regarding their occurrence. This group is mainly composed of products used in everyday life, such as surfactants and surfactant residues, pharmaceuticals and personal care products, gasoline

### Introduction

The analysis of pollutants in environmental samples is complicated by the fact that these compounds are often part of a very complex mixture of hundreds of chemicals and that they are present at extremely low concentrations. Thus, any instrumental technique that is to be used successfully in environmental analysis should allow the separation of such complex mixtures and the identification of the constituents at trace level. Mass spectrometry (MS) is particularly suited for this purpose as it can be coupled with the most important instrumental separation techniques – gas chromatography (GC) and liquid chromatography (LC) – while at the same time it is one of the most sensitive instrumental methods available for the analysis of contaminants. Moreover, it is not only the sensitivity, but also the specificity that makes MS the most powerful instrumental method in environmental analysis.

During the last 10 years the environmental analysis field has changed significantly. Impressive improvements in detection limits are such that parts-per-trillion (ppt) detection is routine for many organic analytes, and detection of a few hundred femtograms of some analytes is now possible, although such detection levels cannot yet be considered routine. Moreover, technologies that have significantly advanced in the last few years include tandem (MS–MS) systems, time-of-flight MS (TOF–MS) and quadrupole-time-of-flight MS (Q–TOF–MS). This article attempts to survey current state-of-the-art in the application of modern mass spectrometric techniques in the environmental analysis.

### Target Compounds

A wide range of man-made chemicals designed for use in industry, agriculture, and consumer goods and

chemicals unintentionally formed or produced as by-products of industrial processes or combustion are potentially of environmental concern. Beside recognized pollutants, numerous new chemicals are synthesized each year and released into the environments with unforeseen consequences. Over the past few decades, analytes having acute toxic or carcinogenic effects and that are persistent in the environment as a result of anthropogenic activity have been widely studied. Examples of these compounds include BTEX (benzene, toluene, and xylene), DDT and its metabolites, polycyclic aromatic hydrocarbons (PAHs), and chlorinated biphenyls (PCBs). While toxic, carcinogenic, and persistent compounds will always be of concern, the last several years have brought an increased interest in endocrine disrupting (ED) compounds – those that interrupt normal hormone function and cause adverse biological effects. ED chemicals encompass a large range of organic, metallic, and organometallic substances (Table 1). There are two classes of substances that can cause endocrine disruption: natural substances (hormone found naturally in the body of humans and animals, and phytoestrogens, substances contained in some plants) and man-made substances. The group of man-made substances comprises synthetically produced hormones designed intentionally to interfere with the endocrine system (e.g., oral contraceptives) and man-made chemicals designed for use in industry, agriculture, and consumer goods that may have unforeseen adverse or synergistic effects. Man-made chemicals also include chemicals unintentionally formed or produced as a by-product of industrial processes or combustion.

Other compounds of interest are the so-called 'emerging contaminants' (Table 1). Emerging contaminants are unregulated contaminants, which may be candidates for future regulation depending on research on their potential health effects and monitoring data regarding their occurrence. This group is mainly composed of products used in everyday life, such as surfactants and surfactant residues, pharmaceuticals and personal care products, gasoline

**Table 1** List of endocrine disruptors and emerging contaminants, analyzed in environmental samples using mass spectrometric techniques

<i>Chemical group</i>	<i>Example</i>	<i>MS technique</i>
Benzenes	Hexachlorobenzene	GC-MS
Bisphenols	Bisphenol A	LC-MS
Chlorinated cyclodienes and camphenes	Chlordane, mirex, toxaphene	GC-MS, HRMS
DDT, derivatives and metabolites	DDT, DDE, tetrachloro-DDT	GC-MS
Disinfection by-products	THMs, HAAs, haloacetonitriles, haloketones, haloaldehydes	GC-MS (EI)
Flame retardants	PBDEs, HBCD, TBBPA	GC-MS (EI and NCI), HRMS
Gasoline additives	Dialkyl ethers, MTBE	GC-MS
Hexachlorocyclohexane and isomers	Lindane	GC-MS
Industrial additives and agents	Chelating agents (EDTA), aromatic sulfonates	LC-MS (ESI)
Organotin compounds	Tributyltin, tributyltin oxide, triphenyltin	GC-ICP-MS, TOF-MS
PBBs	PBB-153, PBB-180, PBB-209	GC-MS (EI and NCI)
PCBs	PCB-77, PCB-153, PCB-169	GC-MS (EI), HRMS
PCDDs/PCDFs	2378-TCDD, 12378-PeCDD, 23478-PeCDF	GC-HRMS (EI), IT-MS
Personal care products	Nitro musks, polycyclic musk, chlorophene	GC-MS (EI and NCI)
Pharmaceuticals	Trimethoprim, erythromycine, sulfamethaxazole, ibuprofene, acetylsalicylic acid, diazepam, estradiol, estrone, estriol	GC-MS (EI and NCI), IT-MS, HRMS, LC-MS (ESI and APCI), MS-MS (ESI and APCI), GC-MS (EI and PCI)
Phthalates	BBP, DEHP, DBP	GC-MS (EI and PCI), LC-MS (ESI)
Surfactants and metabolites	Alkylphenol ethoxylates and carboxylates, NP, OP	GC-MS, LC-MS (APCI)
Triazines and other pesticides	Atrazine, acetochlor, alachlor	

additives, fire retardants, plasticizers, etc. The characteristic of these group contaminants is that they do not need to be persistent in the environment to cause negative effect since their high transformation/removal rates can be compensated by their continuous introduction into environment.

GC-MS and LC-MS are the most commonly used techniques for the environmental analysis of these target compounds. Generally, GC-MS is used for apolar or moderate polar compounds, while for polar compounds LC-MS is the preferred technique. Other compounds are analyzed using both techniques.

## Gas Chromatography-Mass Spectrometry

GC-MS continues to play an important role in the identification and quantification of contaminants in environmental samples. Different mass analyzers, such as linear quadrupole, quadrupole ion-trap, double-focusing sectors, and TOF analyzers, are employed in different applications. Several ionization techniques are also used in GC-MS. Among them, electron ionization (EI) is the most popular because it often produces both molecular and fragment ions. One important feature of EI spectra is that they are highly reproducible, which means that mass spectral libraries can be used for identification of unknowns. However, in some cases, EI does not provide the

sensitivity required for the analysis of very small amounts of compounds in environmental samples. To solve this problem, softer ionization techniques such as chemical ionization (CI) are applied.

A large number of publications have resulted from research on environmental applications of GC-MS. The compounds most commonly analyzed include alkanes, PAHs, pesticides, volatile organic compounds (VOCs) including off-flavor and water disinfection by-products (DBPs), PCBs, polychlorinated dibenzo-*p*-dioxins, and furans (PCDDs/Fs), as well as other ED chemicals such as phthalates and short ethoxy alkylphenol ethoxylate. GC-MS is also the technique of choice for the analysis of emerging contaminants, such as polybrominated diphenyl ethers (PBDEs) or polychlorinated alkanes, as well as for the analysis of some pharmaceuticals and organo-metallic compounds.

## Inorganic Compounds

The analysis of inorganic compounds including metals, mercury, and volatile and nonvolatile organometallics using MS methodologies has been reported in the literature. Inductively coupled plasma (ICP)-MS is enjoying an increasing interest in inorganic trace and ultratrace analysis because of its unmatched sensitivity, elemental specificity, multielement measurement capability, and the possibility of the accurate determination of elemental

isotope ratios. ICP-MS was coupled to GC for speciation analysis in environmental samples, including speciation of organomercury, organolead, and organotin applications. Moreover, GC-ICP-MS is the only technique to date enabling direct speciation analysis of As and Hg in natural gases and gas condensates at the micrograms per liter level. Some recent papers have shown the potential of ICP-TOF-MS for the separation and speciation of organotin and organolead compounds. Detection limits in the femtogram level with good reproducibility were obtained.

### Pharmaceuticals (Steroid Sex Hormones, Human and Veterinary Drugs)

GC-MS has been the technique most commonly implicated in the determination of estrogens in environmental samples. Both conventional MS and ion trap (IT)-MS detection have been accomplished in the EI mode at 70 eV, usually in the selected ion monitoring (SIM) mode, and, in most cases, after sample derivatization, while the use of negative (N)CI has seldom been reported. The sensitivity of GC-MS-MS was reported to be in the range  $20 \text{ pg } \mu\text{l}^{-1}$  (limit of quantification). A recent study has also discussed the possibilities of high-resolution (HR)MS for analysis of steroid sex hormones in environmental samples, showing that, with 20 000 resolution, 10 pg of ethynyl estradiol can be detected. This amount corresponds to a detection limit of 1 ppt if the ethynyl estradiol is in 1 l of water (concentrated into a 0.1 ml extract, followed by injection of 1  $\mu\text{l}$ ).

The often incomplete derivatization of highly polar drugs makes inappropriate their determination by GC. However, a method based on solid-phase extraction (SPE), derivatization by silylation, and detection by GC-MS has been developed for the determination of 22 different neutral and weakly basic drugs belonging to several different medicinal classes like antiphlogistics,  $\beta$ -blockers,  $\beta_2$ -sympathomimetics, lipid regulators, antiepileptic agents, psychiatric drugs, and vasodilators in wastewater as well as in river and drinking water. This method permits detection down to  $5 \text{ ng l}^{-1}$  with recovery rates mostly exceeding 70%.

### Polybrominated Diphenyl Ethers

Several methods for qualitative and quantitative analysis have been developed involving GC-NCI-MS and GC-EI-MS. Until recently, quantitative work has been performed by using technical PBDE products, i.e., Bromkal 70-5DE (BK70), due to the lack of pure reference standards for most PBDE congeners. The major three components in BK70

have been identified as BDE-47, BDE-99, and BDE-100, and only these congeners could be quantified. Since more than 30 PBDE congeners now are available it has become possible to analyze for additional PBDEs (Figure 1). Moreover, the availability of some  $^{13}\text{C}$ -labeled standards allows the development of a methodology based on the quantification by the isotopic dilution method. Previous reports had used other  $^{13}\text{C}$  or  $^{12}\text{C}$ -PCB and other organochlorine surrogates that, in general, give poorer precision and accuracy in the determination of analytes.

Some studies have been carried out comparing the capabilities of the two MS approaches (EI and NCI) for the PBDE determinations. Comparison of detection limits for PBDEs clearly indicates that NCI offers better sensitivity than does EI: NCI-MS gave detection limits between 30 fg and 1.72 pg, whereas EI-MS gave detection limits between 0.53 pg and 32.09 pg. The main advantage of EI-MS is that it provides better structural information. No structural information on the degree of bromination was obtained by NCI. The mass spectra of all PBDEs were dominated by the molecular ion  $[\text{Br}]^-$  and did not show any molecular ion. However, EI provided better structural information, giving the molecular ions and the sequential losses of bromine atoms. Moreover, the use of EI-MS allowed the use of an isotopic dilution method for quantification, making the analysis more reliable at trace levels.

### Polychlorinated Biphenyls

Different determinations of PCBs have been developed. A number of countries have chosen to monitor PCBs as a set of seven indicator PCBs (IUPAC Nos. 28, 52, 101, 118, 138, 153, and 180). These PCBs were analyzed by GC-low resolution (LR)MS. However, when dioxin-like PCBs (non-*ortho* and mono-*ortho* PCBs) were studied, comprehensive analytical procedures are necessary because they occur at concentrations lower than the indicator PCBs mentioned above, and are therefore very elaborate and complicated to analyze. In these cases, a GC-HRMS with quantification by isotopic dilution method was required.

The powerful HRMS instrumentation that is used for the analysis of these contaminants suffers some limitations that are related to the limited accelerating voltage working range for a given group of ions in the SIM mode. For example, co-eluting compounds with wide differences in their masses cannot be effectively monitored in the same window and the chromatographic run thus needs to be prolonged for adequate component speciation. Due to their non-scanning character, TOF-MS is a valuable tool for fast GC because it is able to monitor the entire mass

**Figure 1** GC-NCI-MS-SIM ( $m/z$  79) obtained for a standard solution containing from mono- to hepta-BDEs. Different chromatographic windows could be defined in order to enhance sensitivity.

range in very short times. Different recent studies showed the capabilities of TOF for the analysis of PCBs in different type of samples. Thirty different PCB congeners were analyzed in biological samples above the detection limit in less than 7 min. Routinely around 40 congeners are detected above the detection limit by using SIM on a quadrupole GC-MS in 45 min. The detection limit using the GC-TOF seemed to be somewhat higher.

Another advantage of GC-TOF analyses is that full scan spectra are always acquired. The acquisition of full scan spectra during the analysis opens the possibility of screening for 'unknown' pollutants present in the extracts. A GC-MS-SIM run always need input on the masses to be monitored, and thus this kind of quantitative analysis is restricted to compounds known to be present in the extracts. By using GC-TOF new compounds can be identified by their mass spectra while doing quantitative analysis of known compounds at the same time.

#### Polychlorinated Dibenzo-*p*-dioxins and Furans

MS has been the leading technique used in dioxin analysis. Until the 1990s, ultratrace determinations of polychlorinated dibenzo-*p*-dioxins and furans (PCDDs/Fs) were routinely performed using GC-HRMS, operating in the EI mode (electron energy

$\sim 38$  eV) at 10 000 resolving power. Quantification was carried out by an isotopic dilution technique, based on the addition of known amounts of  $^{13}\text{C}$ -labeled standards.

The application of HRMS has proved to provide the required sensitivity and specificity. The required specificity could be provided by MS-MS as well. While MS-MS with sector or quadrupole instruments needs a series of mass analyzers in space, ITs use one mass analyzer to perform MS-MS in time. Recently, IT-MS was developed to analyze PCDDs and PCDFs. The advantage of IT-MS systems is the much lower price, which could reduce analyses costs. However, sensitivity of IT-MS instruments is considerably lower than of HRMS instruments. The limit of determination for IT-MS systems for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (signal-to-noise ratio 3:1) can be assumed to be in the range of  $\sim 100$ – $300$  fg, whereas modern HRMS instruments have a detection limit of  $\sim 3$  fg.

#### Polycyclic Aromatic Hydrocarbons

Different analytical methods have been published for the PAH determinations. PAHs in environmental samples are usually determined by GC-MS, using both EI and CI modes, or by LC with either fluorescence or diode-array detection. In recent years,

LC-MS using atmospheric-pressure chemical ionization (APCI) has been seldom used for the PAH analyses. However, detection limits obtained using LC-MS were approximately one order of magnitude higher than those obtained by GC-MS.

In the last few years, new procedures were developed for PAH analysis using MS-based detection methods. GC-IT-MS and a laser desorption-IT-MS screening method were applied to the analysis of airborne particulate-associated PAHs. Direct screening of aerosol filter samples were carried out using laser desorption TOF-MS. Isotope dilution techniques using GC-MS were also developed for some PAHs, such as benzo[a]pyrene.

### Surfactants

Numerous GC-MS applications for the analysis of surfactants have come into focus since the early 1960s when the first GC papers on separation of nonionic surfactants were published. However, the major drawback for application of GC to surfactants is their lack of volatility.

Among different nonionic surfactant classes, alkylphenol ethoxylates (APEOs) comprise the class meriting special attention with respect to environmental issues. The analysis of underivatized alkylphenolic compounds by GC-MS is restricted to the most volatile degradation products, such as alkylphenols and APEOs with less than 4-ethoxy groups. To overcome the problem of volatility, different offline and online derivatization protocols have been developed. Two complementary MS techniques, one using EI and another using the less commonly used positive (P)CI, have been evaluated for the analysis of APEOs, their acidic (APECs) and neutral metabolites (APs), and halogenated derivatives.

Linear alkylbenzene sulfonates (LAS) are the most commonly used anionic surfactants; however, as nonvolatile compounds, they cannot be analyzed directly by GC-MS and pretreatment is required to form volatile derivatives. Capillary GC of derivatized (or desulfonated) LAS allows separation according to alkyl chain length, with the highest chain lengths giving longer retention times and with internal isomers of each homolog eluting first. The higher separation efficiency of GC over LC has been particularly useful to study the mechanism of biodegradation of homologs and isomers in laboratory-scale experiments.

### Volatile Organic Compounds

Miniature instrumentation and field portability is an area of increasing interest in MS. These instruments were ideal for a variety of *in situ* analysis in environmental applications. *In situ* analysis of volatile

organic compounds (VOCs) is a good option because it can solve the problems related with sampling, evaporative loss, and transport. For instance, a GC-MS field instrument has been used for the analysis of BTEXs in urban outdoor environments. The mass analyzer most frequently used in GC-MS field instruments is the linear quadrupole due to its simplicity, small size, durability, and compactness. However, other analyzers were also tested. Direct sampling IT-MS systems were evaluated for monitoring trace levels of halogenated VOCs in air samples. It was found that this method offers comparable results with those obtained using MS(SIM) and MS-MS operation modes.

In water, GC-MS is coupled to purge and trap or headspace sample preparation for the analysis of VOCs like BTEX and MTBE. Another important group of volatile analytes in water are DBPs. Attention has been directed to volatile chlorinated compounds such as trihalomethanes (THMs), as well as other semivolatile compounds such as haloacetic acids (HAAs), haloacetonitriles, halo ketones, and haloaldehydes. The methods used to determine these compounds include GC-EI-LRMS, where a after derivatization step is necessary due to the low volatility and high polarity of these analytes. Using this technique, limits of detection were in the microgram per liter range.

The most obvious taste and odor compounds, such as hydrocarbons, solvents, iodoforms, and various chloro- and bromophenols, which have odor thresholds in the microgram per liter range, are currently analyzed by GC-EI-MS using quadrupole instruments.

## Liquid Chromatography-Mass Spectrometry

Currently, the main breakthrough in environmental analysis is observed in the application of LC-MS and LC-MS/MS techniques. One of the obstacles to routine analytical applications of LC-MS had been the unavailability of rugged and reliable LC-MS interfaces. The development of atmospheric pressure ionization (API) overcame such limitations as poor structural information or sensitivity seen with thermospray (TSP) or particle-beam (PB). API is used as a generic term for soft ionization obtained by different interface/ionization types, such as APCI and electrospray (ESI) that operate under atmospheric pressure conditions. Today, LC-MS has become a routine analytical tool, allowing the detection of polar and nonvolatile compounds not amenable to GC analysis.

## Pesticides

Most of the modern pesticides and their degradation products are characterized by medium to high polarity and thermal lability. Neutral and basic compounds (phenylureas, triazines) are more sensitive using APCI (especially in positive ion mode), while cationic and anionic herbicides (e.g., bipyridylium ions, sulfonic acids) are more sensitive using ESI (especially in negative ion mode). Based on comparative analysis of 75 pesticides, the so-called ionization-continuum diagram illustrates the relationship between compound acidity and appropriate ionization modes (Figure 2).

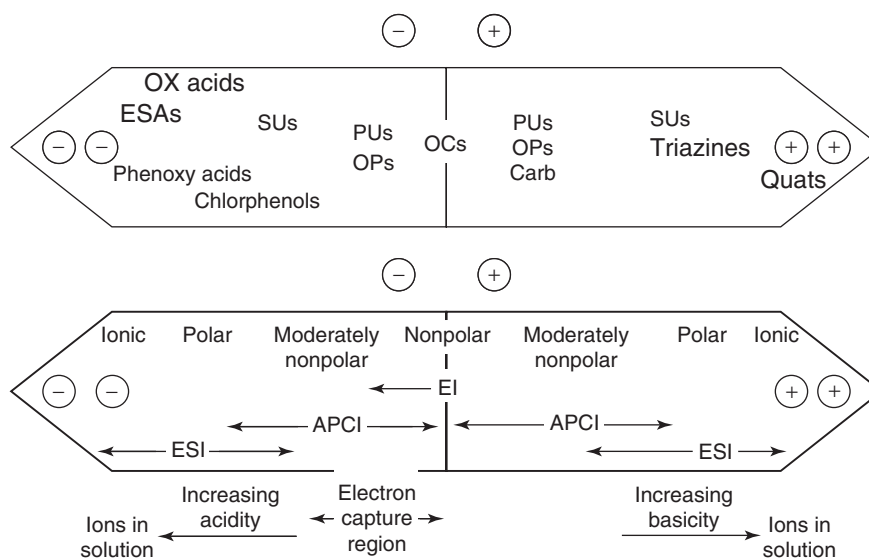

Some studies have reported the possibilities of screening surface water and identification of water pollutants using a modern data acquisition of Q-TOF-MS, such as data-dependent MS to MS-MS switching. Additionally, online SPE followed by LC with the combination of orthogonal-acceleration TOF-MS is also shown to be a powerful tool in the determination of pesticides from various compound classes in surface water in the concentration range of  $0.1\text{--}10\text{ }\mu\text{g l}^{-1}$ . LC-TOF-MS seemed to be a promising method for the identification of the unknown pesticides or their degradation products, which were almost impossible by a single quadrupole LC-MS. The TOF-MS gives the accurate mass of the molecular ion, which in turn may be used to determine the empirical formula of the unknown compound. This is helpful in the determination of pesticides, when no standards exist, especially for the ones where the mass of the molecular ion is typically less than 350 amu.

## Steroid Sex Hormones and Other Pharmaceuticals

The principal analytical methods employed in the analysis of pharmaceuticals in aqueous environmental samples include both GC and LC coupled to MS or MS/MS. In general, LC-MS methods have demonstrated lower relative standard deviations than GC-MS methods that have derivatization prior to analysis. LC-ESI-MS/MS is presented as the technique of choice for polar, unstable, and high molecular mass compounds, such as most pharmaceuticals and their metabolites. MS detection has preferably been performed with the ESI interface. An analytical protocol applying LC-ESI-MS/MS with previous filtration of the water sample, with addition of  $\text{Na}_2\text{EDTA}$  to avoid complexation of analytes (especially tetracyclines) with metals present in the water, was proposed for the analysis of antibiotics corresponding to the classes of macrolides, sulfonamides, penicillins, and tetracyclines in water samples.

For LC-MS determination of estrogens, ESI operating in the negative ion mode of ionization has been the most widely used interface because of its observed better sensitivity compared to the same interface operating in the positive ion mode of ionization and to APCI.

In the LC-MS analysis of estrogens, selected ion monitoring of the  $[\text{M}-\text{H}]^-$  ion in ESI (NI) and the  $[\text{M} + \text{H} - \text{H}_2\text{O}]^+$  ion ( $[\text{M} + \text{H}]^+$  for estrone) in APCI (positive) is usually carried out for maximum sensitivity. Progestogens can be determined in the positive ion mode of operation with both ESI and APCI. However, the sensitivity achieved with the

**Figure 2** Ionization continuum diagram showing the interrelationship between pesticide properties and the appropriate API mode. (Reprinted with permission from Thurman EM, Ferrer I, and Barceló D (2001) *Analytical Chemistry* 73: 5441; © American Chemical Society.)

APCI interface is about 10-fold lower than that of the ESI interface. Application of MS-MS improves the sensitivity of the detection (limits of quantification  $5 \text{ pg } \mu\text{l}^{-1}$ ) as compared to LC-MS (limits of detection  $200 \text{ pg } \mu\text{l}^{-1}$ ).

### Surfactants

Owing to the anionic character of LAS, LC coupled with an ESI-MS operated in negative mode is

particularly attractive for the quantitative determination of this surfactant type. LAS analysis by ESI-MS under negative conditions led to mass spectra with the four  $[\text{M}-\text{H}]^-$  ions of  $m/z$  297, 311, 325, and 339, corresponding to the LAS homologs C10–C13, respectively. With increasing cone voltage, additional fragment ions at  $m/z$  183 and 80 were obtained, which were assigned to styrene-4-sulfonate and  $[\text{SO}_3]^-$ , respectively. No side chain-specific

**Figure 3** Product ion scan of (A) NP with  $m/z$  219 and of (B) NPE<sub>1</sub>C with  $m/z$  277 and the proposed fragmentation scheme under CID conditions obtained using argon as collision gas at collision energy of 40 eV. Note: the exact branching of the alkyl chain is unknown and the alkyl isomer shown here is just one of several possibilities.

fragment ions were produced under API conditions; thus a mass spectrometric distinction of positional isomers of LAS could not be achieved. Though the sulfonate group of LAS is quite acidic, the long hydrophobic alkyl chain provides sufficient retention in RPLC; however, the more polar carboxylated degradation products, the sulfophenyl carboxylates (SPCs), require additives such as triethylamine or tetraethylammonium acetate for a sufficient retention. To avoid LC conditions involving the use of ion-pairing agents, because of their adverse effects on the process of ion formation, an alternative method based on the conversion of the carboxylic groups into methyl esters, which resulted in successful separation and a 10-fold enhancement of the sensitivity of the ESI-MS detection, was proposed.

During the 1990s, LC-MS and LC-MS/MS have become a routine method for analysis of alkylphenolic nonionic surfactants and their potentially estrogenic degradation products. In normal-phase systems, the APEOs are separated according to the increasing number of ethylene oxide units, while corresponding oligomers with the same number of ethoxy units but different alkyl substituents (e.g., nonylphenol ethoxylates (NPEOs) and octylphenol ethoxylates) coelute. Normal-phase LC-ESI-MS was used for the quantitative determination of individual NPEOs since complete chromatographic separation of NPEO oligomers is achieved using gradient elution with nonpolar solvents. However, such mobile phases are not compatible with ESI, and post-column addition of a polar solvent and a modifier is required to facilitate ionization of the target analytes and thus to enhance the signal and system stability. On the other hand, RPLC allows separation according to the character of the hydrophobic moiety and it is particularly well suited to separate surfactants containing various hydrophobic moieties (separation of alkyl homologs). In this case, the length of the ethylene oxide chain does not influence the separation and the various oligomers containing the same hydrophobic moiety elute in one peak.

The typical MS spectrum of polyethoxylates yields a characteristic pattern of equally spaced signals with mass differences of 44 Da (one ethylene oxide unit), which is a diagnostic fingerprint for this group of compounds. The nonionic surfactants easily form adducts with alkaline and other impurities. Using an ESI interface and aprotic solvent APEOs predominantly give evenly spaced sodium adducts  $[M + Na]^+$  due to the ubiquity of sodium in the solvents and surfaces. Sodium adducts are relatively

stable and generally no further structurally significant fragmentation is provided in the mass spectrum. However, formation of distinct adducts with ions originating from the buffer, the sample, and/or the introduction system (e.g.,  $H^+$ ,  $Na^+$ ,  $K^+$ ), water clusters (especially when using APCI interface), dimeric complexes, and doubly charged ions, such as disodium adducts, are also reported.

When using MS/MS and more selective multiple reaction monitoring detection, it is recommended that the formation of sodium adducts is suppressed, as these fragment poorly. ESI-MS/MS permits unambiguous identification and structure elucidation under negative ionization conditions of acidic alkylphenolic compounds (i.e., APECs) and fully deethoxylated alkylphenols. An example of MS/MS spectra of NP and NP<sub>1</sub>EC is shown in Figure 3.

## Food Applications

### Introduction

Mass spectrometry (MS) is a very versatile technique with an established and rapidly growing record of successful applications in the food and nutrition sciences. Major advances in organic MS over the last decade, include the refinement and widespread adoption of electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) MS. These techniques have substantially extended the scope of mass spectrometric applications in the food and nutrition sciences. Furthermore, alternative mass spectrometric techniques, including isotope ratio MS (CIRMS), inductively coupled plasma MS (ICP-MS), proton transfer reaction MS (PTR-MS), and accelerator MS (AMS) are having an increased impact in the study of food authenticity, nutrient metabolism, and, in the case of PTR-MS, flavor research. This article will briefly review applications of MS in the analysis of a wide range of food components, including nutrients, structural constituents of foods, flavors, biologically active nonnutrients, and toxicants.

### Sample Preparation

Sample preparation techniques vary from rudimentary to elaborate because of the very wide range of analytical problems presented in food analysis and research. Preparation methods are highly dependent on both the nature of the analyte and on the type of mass spectrometric procedure used. At one extreme, the processing of food samples prior to pyrolysis MS (PyMS) may entail little more than the drying of a few micrograms of material, followed by introduction of the sample into the mass spectrometer on a pyrolysis probe. Flavor components are frequently isolated by solvent extraction, headspace sampling, or solid-phase microextraction (SPME), or in the case of PTR-MS analysis, simply by direct sampling of volatile components of the analyte. In contrast, linkage analysis of cell wall polysaccharides in food plants requires extensive chemical derivatization before samples are analyzed by gas chromatography-mass spectrometry (GC-MS). Combined liquid chromatography-mass spectrometry (LC-MS) and tandem mass spectrometry (MS/MS or MS<sup>n</sup>)

can sometimes be conducted on samples that have undergone minimal preparation. Finally, sample preparation for inorganic MS, zinc or chromium in food or biological fluids, for example, can be highly demanding because it is essential to avoid contamination.

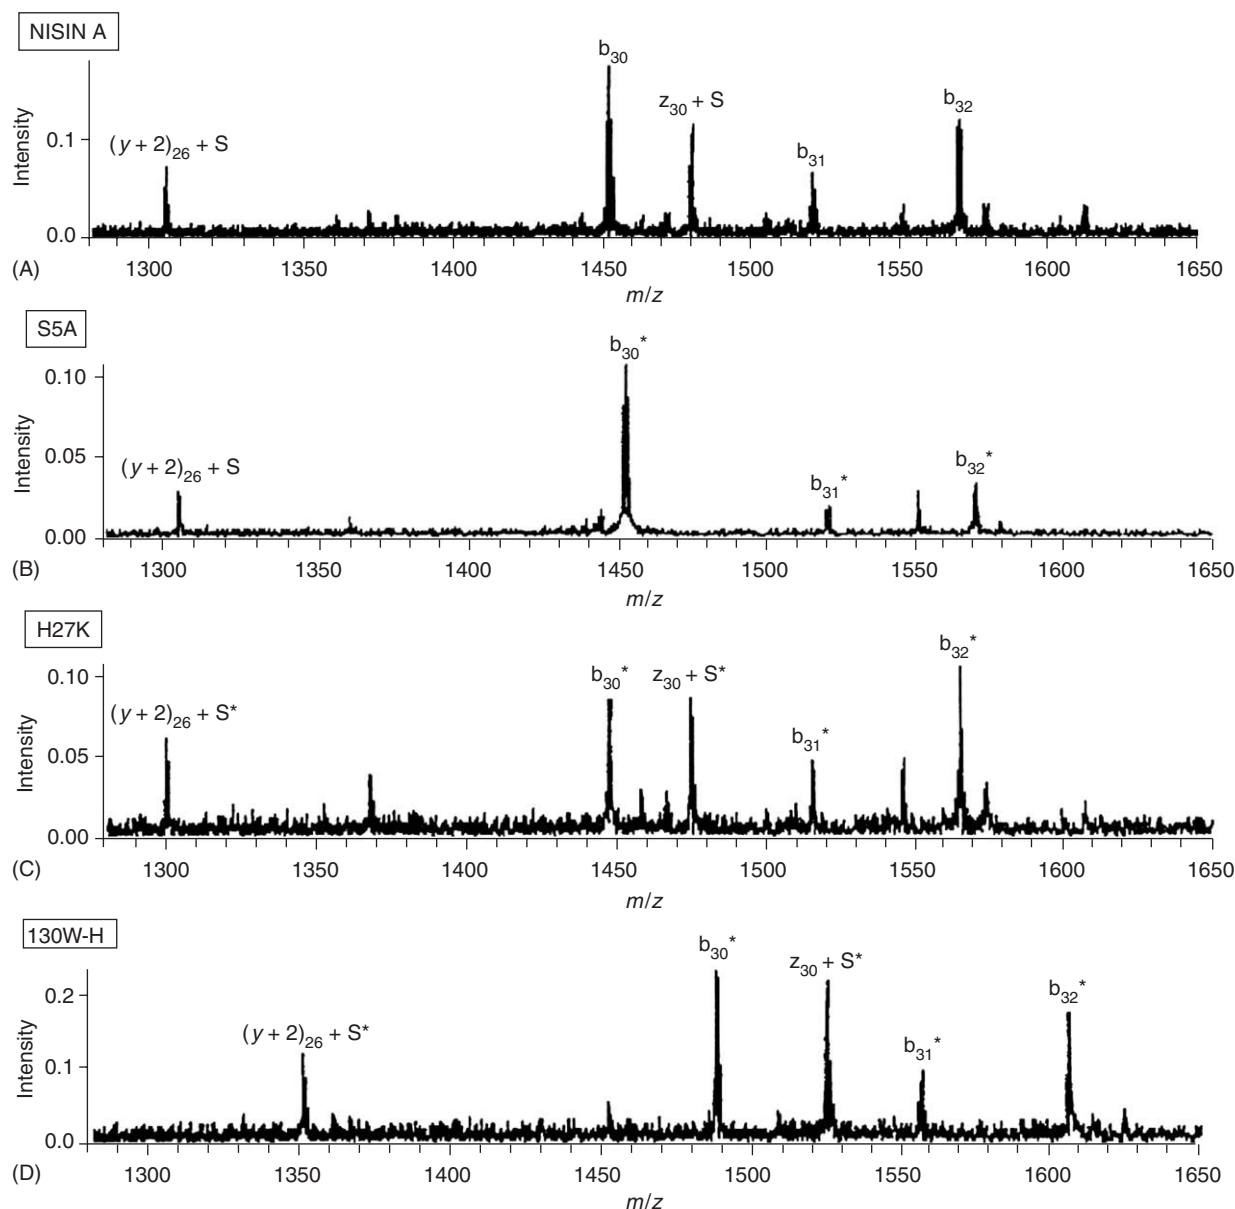

### Major Food Components

#### Amino Acids, Peptides, and Proteins

The analysis of amino acids by GC-MS of suitable volatile derivatives is a well-established technique. Despite the availability of amino acid analyzers, GC-MS is still occasionally used because it is useful for qualitative and quantitative analysis of unusual (i.e., nonprotein) amino acids. GC-MS is also valuable for conducting studies of the racemization of amino acids during cooking or food processing, when used in conjunction with chiral GC columns and deuterium labeling. GC-MS methods are also often used for determining stable isotope labeled amino acids in nutritional, metabolic studies. ESI LC-MS may also be used for determining amino acids.

Peptides and proteins are of interest in several areas of food and nutrition science, including allergenic response, food material properties, flavorings, toxicology, and nutritional value. An increasing number of analytical papers in the food and nutrition field now describe applications of modern MS techniques such as ESI and MALDI-TOF for molecular weight determination or (in MS/MS mode) full or partial sequencing. The variety of applications appearing in the current literature is also impressive: representative examples include the effects of irradiation on egg proteins, pH-related conformational changes in egg lysozyme, measurement of lactosylation of whey proteins, determination of the heterogeneity of casein proteins, authentication of cheeses by determining protein profiles, characterization of flavor peptides in protein hydrolysates, quantification of wheat gliadins, characterization of soya and other legume proteins, and the characterization of the food preservative peptide antibiotic nisin, its genetically modified variants and its inactivation by glutathione by Fourier transform ion cyclotron resonance (FT-ICR) MS and MALDI-TOF, respectively. **Figure 1** shows a comparison of the sustained off-resonance irradiation collisionally activated decomposition (SORI-CAD) spectra of 'wild-type' nisin A and three genetically modified variants. The ions shifted in mass (marked by an asterisk) relative to the wild-type

**Figure 1** Comparison of parts of the SORI-CAD ESI FT-ICR mass spectra of the  $[M + 3H]^{3+}$  precursor ions of (A) nisin A (wild-type nisin), (B) nisin S5A, (C) nisin H27K, and (D) nisin I30W-H, showing the region containing doubly charged fragment ions. The ions in the transgenic variants that are shifted in mass compared to nisin A are marked with asterisks. (Reprinted from Lavanant H, Heck A, Derrick PJ, *et al.* (1998) Characterization of genetically modified nisin molecules by Fourier transform ion cyclotron resonance mass spectrometry. *European Mass Spectrometry* 4: 405–416, with permission; © IM Publications.)

molecule are clearly visible and were used to aid structural confirmation of the variant molecules.

### Carbohydrates and Sugars

Carbohydrate analysis is of great importance in the food sciences because of the significant role of polysaccharides as macronutrients, as major constituents of dietary fiber, and as food structure components contributing to textural properties, and food additives. Because of structural similarities between

many monosaccharide residues, detailed mass spectrometric analysis is more difficult than for other biopolymers. Furthermore, the anomeric configuration and the nature of the linkages between sugar residues cannot generally be determined directly by MS. Many different schemes are available to convert sugars to derivatives sufficiently volatile for GC–MS analysis. These often involve trimethylsilylation or a combination of this derivatization technique with oxime formation. A classic method for compositional and linkage analysis of large polysaccharides

involves GC-MS of partially methylated alditol acetates (PMAAs). Polysaccharides are methylated, hydrolyzed, and reduced with NaBD<sub>4</sub> to deuterated O-methyl alditols, which are then acetylated and analyzed qualitatively and quantitatively by GC-MS. PMAAs yield characteristic mass spectra that allow determination of the number, nature, and linkage position of the monosaccharides that comprise the polysaccharide.

The molecular weights of large polysaccharides can be measured with the aid of ESI, in LC-MS, capillary electrophoresis/mass spectrometry (CE-MS), or direct injection modes, and by MALDI MS. For example, MALDI-TOF analysis of fructooligosaccharides has enabled the development of a rapid method for analyzing these molecules in food plants. Examples of other important applications of organic MS in food carbohydrate analysis include determination of the structures of plant oligosaccharides that may be involved in eliciting allergic response and direct analysis of plant cell wall xyloglucans.

Concerns over the adulteration of high value foods, for example, dilution of maple syrup, fruit juices, or of protected denomination of origin honeys with corn syrup, have been addressed for some time by combusting food samples and then measuring <sup>13</sup>CO<sub>2</sub>/<sup>12</sup>CO<sub>2</sub> ratios by high-precision IRMS. Subtle differences in isotope ratio are found in sugars derived from different sources and this property can be used to confirm their origin. Figure 2 exemplifies this by demonstrating the linear relationship between δ<sup>13</sup>C‰ and the ratio of an adulterant sugar, high fructose corn syrup, to honey sugar.

**Figure 2** Plot of changes in <sup>13</sup>CO<sub>2</sub>:<sup>12</sup>CO<sub>2</sub> ratio (δ<sup>13</sup>C‰, defined in text) of honey against concentration of high fructose corn syrup adulterant. (Reproduced with permission from PDZ Europa, Norwich, UK.)

δ<sup>13</sup>C‰ is a measure of natural carbon-13 levels against a reference standard and is defined by the equation:

$$\delta^{13}\text{C}\text{‰} = \left[ \frac{{}^{13}\text{C}/{}^{12}\text{C}_{\text{sample}}}{{}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}} - 1 \right] \times 1000$$

## Lipids

Dietary lipids may be analyzed mass spectrometrically as long-chain fatty acids, esters, triglycerides, and phospholipids. Although the degree of unsaturation of fatty acids may be determined readily from electron ionization (EI) mass spectra, double bond location presents a more challenging problem. Long-chain unsaturated fatty acids rearrange extensively under EI, so fragment ions do not yield reliable information regarding double bond position. A number of strategies have been devised to overcome these problems: one of the most popular is derivatization followed by GC-MS. Several different procedures are available, for example, oxidation followed by silylation, epoxidation, and the analysis of methoxy or dimethyldisulfide derivatives. Alternatively, chemical derivatives that localize charge may be generated, thus preventing charge-induced double bond migration. A good example is the formation of volatile 2-substituted 4,4-dimethyloxazoline derivatives by condensation of the fatty acid with 2-amino-2-methylpropanol. The 'charge-localizing' derivative is sufficiently volatile for GC-MS analysis and yields ion clusters separated by 14 Da, reducing to 12 Da when a double bond interrupts the chain. Alternative techniques for locating double bond position include high collision energy 'charge-remote' MS/MS fragmentation of molecules ionized by negative-ion chemical ionization (CI). Possible alternative techniques employ ESI of lithiated adducts of unsaturated fatty acids and low-energy MS/MS and acetonitrile CI ion trap MS/MS of polyunsaturated fatty acid methyl esters.

Capillary GC-MS is useful for identifying the carbon and unsaturation number of acylglycerols. However, APCI LC-MS can be used to analyze less volatile acylglycerols that may be unsuitable for GC-MS. APCI LC-MS has become the method of choice for qualitative and quantitative analysis of acylglycerols and, when combined with MS/MS, is capable of distinguishing fatty acid chains in the sn-2 position from those in the sn-1/3 positions.

The sensitivity, selectivity, and convenience of positive and negative-ion ESI LC-MS makes this the current benchmark technique for analyzing phospholipid mixtures. Additional structural information can be obtained by MS/MS. Where these advanced

techniques are unavailable, a more laborious approach of chromatographic class separation, chemical degradation, and GC-MS analysis of fatty acid can be used to generate useful structural information.

### Complete Foods and Food-Related Materials

PyMS is capable of generating useful data on intact foodstuffs or associated microorganisms (food poisoning bacteria, for example). PyMS is based on the controlled thermal degradation of samples under inert conditions to produce mixtures of volatile compounds that are swept into the mass spectrometer ion source and ionized by EI or CI. The resulting 'fingerprint' spectrum of the analyte contains characteristic features that can be classified by chemometric methods. Pyrolysis is sometimes combined with GC-MS in order to extract more information from the analyte. Applications of PyMS in the food sciences include quality assurance and authentication of food and drinks, analysis of cell wall material in food plants, and identification of food microorganisms.

Direct analysis of microorganisms, including food poisoning microorganisms, has also been conducted by MALDI-TOF MS. This promising technique can be used to characterize bacteria rapidly by genus, species, and strain.

### Flavors and Taints

Because most flavor components are highly volatile, EI and CI GC-MS have been primary techniques in flavor analysis and research since the early 1960s. For example, ~1000 discrete compounds have been identified in coffee volatiles using capillary GC-MS methods.

The ease with which SPME GC-MS studies may be conducted has made this an important and useful technique for sampling flavors and taints. GC-MS has been supplemented by LC-MS techniques for studying involatile flavor precursors or semivolatile or involatile food components that have important flavor characteristics.

The availability of a large knowledge base of flavor profiles (largely defined by GC-MS analysis) and recent instrumental advances have resulted in a shift in emphasis of mass spectrometric applications in flavor research. Instead of characterizing complex mixtures of volatiles, several researchers are now focusing on flavor release and, more specifically, on sampling volatiles released into the mouth and nose. By using a special APCI probe coupled to a mouth or nose piece, it is possible to conduct dynamic, breath-by-breath analyses of air expired during eating. The recent development of PTR-MS for online trace gas monitoring has considerable potential for application

to flavor research because of its ability to sample air directly. PTR-MS has already been applied to analysis of flavor compounds. Other food-related applications include the control of food production by determining volatile organic compounds produced during fruit ripening and aging, the study of coffee volatiles and monitoring of meat degradation.

Mass spectrometric methods are also useful for authenticating flavor components, using methods for accurately measuring  $^{13}\text{CO}_2/^{12}\text{CO}_2$  ratios, similar to those already described for authenticating sugars (above). If more detailed analysis is required GC/combustion/isotope ratio MS will yield accurate isotope ratios on individual components of a flavor sample.

## Nutrition Studies

### Stable Isotope Methods

Interest in the use of stable isotope MS for studying both the nutritional value of foods and diets and fundamental aspects of nutrient metabolism in humans has increased considerably. The only major drawbacks of stable isotope studies are associated with the presence of endogenous isotopes of the elements under investigation. Sufficient label must be administered to generate a measurable increase in isotope ratio. However, care is needed to ensure physiological dosing as administration of excessive doses yield physiologically contentious data. Conversely, administration of small quantities of label requires careful and accurate measurement of isotope ratios because the enriched material is diluted by the endogenous nutrients. In the case of mineral metabolism studies, additional precautions are necessary because of the possibility of contamination during sample processing.

Stable isotope studies usually involve administration of the enriched stable isotope in or with a meal. The method of labeling depends on the type of study undertaken. For elements such as selenium, where absorption and metabolism are highly dependent on chemical form, it is usually necessary to use an intrinsic label (i.e., one that is biosynthetically incorporated into the food). Conversely, minerals believed to form a 'common pool' in the digestive system may be mixed directly with the food (extrinsic labeling). In some cases a second isotope is injected or infused intravenously to correct for endogenous losses. Samples of breath, blood, urine, saliva, or feces are then collected for an appropriate period and subjected to isotopic analysis. Isotope ratio measurement often requires specialized instrumentation such as

high-precision IRMS or dedicated inorganic instruments such as ICP-MS.

### Mineral Nutrients

Although several different mass spectrometric methods have been deployed to determine enriched stable isotopes in human studies of nutrient mineral metabolism, thermal ionization mass spectrometry (TIMS) and particularly ICP-MS are now used almost exclusively. ICP-MS is rapid, very sensitive, and sample preparation and introduction is often simplified. Furthermore, ICP-MS can be coupled directly to separation techniques such as size-exclusion chromatography (SEC), high-performance liquid chromatography (HPLC), or CE so that speciation, the determination of the chemical form of particular elements, may also be studied. The two major drawbacks of ICP-MS, low precision relative to TIMS and interference from polyatomic ions in the argon plasma, have largely been overcome by new generations of instruments equipped with multiple collectors and collision/reaction cells, respectively.

A wide range of human studies has been conducted using enriched stable isotopes of nutrient minerals. Applications include the determination of the absorption and metabolism of iron, zinc, calcium, copper, selenium, and molybdenum. An example of the type of information that can be obtained is provided by a study of iron absorption from different weaning foods, and the effects of vitamin C on iron absorption. These measurements, conducted using enriched stable isotopes of  $^{57}\text{Fe}$  and  $^{58}\text{Fe}$ , demonstrated a doubling of iron absorption when a drink containing 50 mg of vitamin C was administered with the food.

A recent development, especially useful for conducting long-term studies of the effect of diet on metabolism, is to administer extremely low levels of long-lived radioisotopes, e.g.,  $^{41}\text{Ca}$ , that are then measured by AMS. Because the activity of the radioisotope is extremely low (typically  $<10^{-6}$  of annual background radiation dose), it is considered to be safe for human use. AMS opens up the exciting possibility of conducting long-term metabolic and dietary intervention studies where required; for example, in studies of bone metabolism.

### Vitamins

Although vitamins can be determined, both qualitatively and quantitatively, by MS, routine analysis is usually best conducted by other means (e.g., HPLC with ultraviolet (UV) or fluorescence detection, immunoassay methods, or microbiological methods). Analytically, MS does have an important role as a reference technique, especially when used in isotope

dilution-based analyses, for evaluating and calibrating alternative, non-MS techniques. However, the most prominent role for MS in vitamin research is in studies of the metabolism of vitamins in humans, especially by LC-MS or LC-MS/MS. The newer LC-MS techniques of APCI and ESI are particularly useful in this respect because many vitamins are too labile for EI and CI MS.

Vitamins  $\text{D}_2$  and  $\text{D}_3$  and their major metabolites have been studied extensively by GC-MS of volatile derivatives; these studies include quantitative determination by isotope dilution. More recently, ESI LC-MS and LC-MS/MS have been used in the qualitative and quantitative measurement of vitamin D and vitamin D analogs.

The association of folates with reduced chronic disease risk and prevention of neural tube defects has generated increased interest in studies of the metabolism of these B group vitamins. Recent activity has focused on developing improved mass spectrometric methods for determining the absorption, metabolism, and bioavailability of these molecules. The folates are polar, involatile molecules that are unstable in solution and must be derivatized if they are to be analyzed by EI or CI MS. Pioneering studies of the human metabolism of folates were first conducted by selected ion monitoring (SIM) GC-MS of derivatized extracts from biological fluids. Although the GC-MS method has provided useful data on the kinetics of folate metabolism and on urinary excretion of folate and metabolites, the method has several drawbacks. Improvements both in mass spectrometric techniques and in speed of analysis were clearly desirable and a number of groups have focused on developing LC-MS methods. Negative-ion ESI techniques developed to determine the four main food and supplementary folates, folic acid, 5-methyltetrahydrofolic acid, tetrahydrofolic acid, and folinic acid, in selected foodstuffs and a vitamin supplement demonstrated the feasibility of using ESI LC-MS in folate analysis. Other laboratories have subsequently reported successful measurement of stable isotope labeled folates in human plasma and/or urine by positive-ion ESI LC-MS, negative-ion LC-MS/MS (in multiple reaction monitoring mode), and SIM negative ion LC-MS. Limits of quantification were sufficient to conduct human metabolic studies using  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^2\text{H}$  folates, labeled both extrinsically and intrinsically, on spinach and fortified cereal grain. The low-collision-energy negative-ion tandem ESI mass spectrum of 5-formyl tetrahydrofolate is shown in Figure 3.

AMS has also been used to determine the metabolic fate of folates labeled with low levels of the radioactive isotope  $^{14}\text{C}$ .

**Figure 3** The MS/MS product ion spectrum of  $m/z$  472, the  $[M - H]^-$  ion of 5-formyl tetrahydrofolate, at a collision energy of 35 V. (© Institute of Food Research, reproduced with permission.)

The ability to conduct bioavailability studies on foods labeled intrinsically with stable isotopes is particularly important as this type of labeling is the 'gold standard' for metabolic studies, i.e., intrinsic label should mimic the behavior of endogenous nutrients most closely. However, the mass spectrometric measurement of the metabolism of intrinsically stable isotope labeled materials is far more challenging than measuring extrinsically labeled nutrients. Low levels of isotope incorporation must be determined in small samples and it is only quite recently that modern LC-MS and LC-MS/MS methods, as demonstrated by the folate studies described above, have begun to rise to this challenge.

Vitamin A is a generic descriptor for a family of fat-soluble vitamins that has the biological activity of retinol, one of the most active and bioavailable members of the group. Retinol, retinoids, and their derivatives yield characteristic EI spectra, a property that has been exploited for over 25 years by GC-MS methods that determine liver stores of retinol non-invasively, following oral administration of deuterated retinol. A simple mathematical formula derives liver stores of retinol from isotope composition in plasma. Various EI and positive ion CI GC-MS procedures have been used; the most successful techniques involve measurement of silylated derivatives of retinol. Although these methods have provided useful nutritional data, further improvements in sensitivity were still desirable for conducting serial infant studies or when sampling under nonideal field conditions. A technique based on negative ion

electron capture GC-MS of trimethylsilyl derivatives fulfills these increased demands and yields. The method worked on 200  $\mu$ l blood samples, the amount of blood typically collected in a heel-prick sample from an infant, and yielded measurements on enrichments as low as 0.01% of circulating retinol- $D_8$ . More recently, both APCI LC-MS and LC-MS<sup>n</sup> methods have been developed to measure retinol conjugates such as retinyl palmitate (which appears in the blood soon after vitamin A containing meal is consumed). These techniques have advantages over GC-MS methods because there is no need to hydrolyze samples to release free retinol, or for derivatization for GC-MS. Carotenoid (pro-vitamin A) metabolism is also being studied by LC-MS techniques because of epidemiological evidence of their putative role in cancer prevention. Although ESI LC-MS has shown promise in preliminary mass spectrometric studies, APCI LC-MS is now the method of choice because of its robustness and tolerance of a wider range of organic solvents.

Many other vitamins have been determined by mass spectrometric methods; representative examples include APCI LC-MS/MS measurement of tocopherols and LC-MS measurement of K vitamins.

## Trace Components in Foods

### Food Additives

Food additives comprise a wide variety of compounds that are generally monitored by techniques

other than MS; however, occasional quantitative applications do occur, exemplified by GC–MS determination of antioxidants in stored products.

### Biologically Active Nonnutrients (Dietary Phytochemicals)

Biologically active (bioactive) nonnutrients in foods comprise a wide range of phytochemical substances. Lack of space permits discussion of mass spectrometric analysis of only a small range of these compounds here.

Glucosinolates (Figure 4) and their biologically active breakdown products are found in many plant foods. More than 100 different types of glucosinolate have been isolated from plants. Although some glucosinolates may have toxic (e.g., goitrogenic) properties, they are known to be potent inducers of Phase II enzymes that protect against carcinogens and other toxic electrophiles.

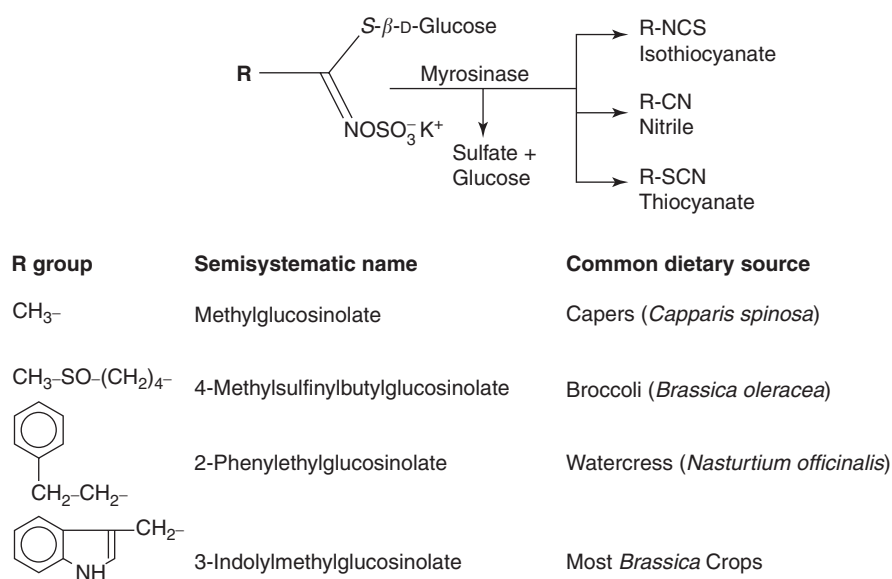

The structural variability is in the aglycone, R that may comprise linear or branched alkyl and alkenyl side chains, alcohols, methylthioalkyl, methylsulfinyl, aralkyl, or heterocyclic groups. GC–MS is a useful mass spectrometric technique for analyzing volatile glucosinolate breakdown products. Negative-ion ESI LC–MS is now the method of choice for determining intact glucosinolates and positive ion APCI LC–MS for analyzing the more thermally labile breakdown products (e.g., sulforaphane) and their human metabolites. ESI LC–MS and MS/MS are also useful for conducting metabolic studies, for example, by detecting and determining glutathione

conjugates of isothiocyanate breakdown products of glucosinolates.

Phenolics are a distinctive feature of all plant tissues and are of interest because they can affect palatability, taste, nutritional value, and particularly the health properties of foods. For example, the flavonoids occur very widely in plants and there is great interest in their role as protective factors in the diet. More recently, the modern methods of LC–MS analysis, APCI and electrospray, have been applied to the detection and quantification of flavonoids and isoflavonoids. Although early mass spectrometric techniques for analyzing these molecules focused on GC–MS methods (after appropriate derivatization), the newer LC–MS methods are now widely used. For example, isoflavones and their conjugates have been determined in soy foods by positive and negative ion APCI LC–MS. ESI and APCI LC–MS methods are also now used for conducting studies of flavonoid metabolism, by following the disappearance and deconjugation of flavonoid glycosides and the appearance of glucuronides, sulfates, and methylated metabolites.

### Natural Toxicants

Mycotoxins secondary metabolites produced by *Aspergillus* (aflatoxins) and *Fusarium* (tricothecenes, etc.) food-spoilage molds comprise two of the most prominent groups of natural toxicants. Many different mass spectrometric techniques, including EI, positive and negative ion CI, GC–MS, LC–MS, supercritical fluid chromatography/mass spectrometry, and

**Figure 4** General structure of the glucosinolates and their common myrosinase hydrolysis products. (Reproduced with permission from Institute of Food Research; © Institute of Food Research.)

MS/MS have been devised to monitor the levels of mycotoxins in foods, body fluids, and tissues. The most recent developments include ESI LC-MS determination of aflatoxins down to low picogram levels. Additional selectivity was provided by MS/MS selected reaction monitoring. Examples of other naturally occurring food toxicants determined with the aid of MS include mutagenic compounds related to quinoxaline that may be formed in cooked meats. The most notorious recent example of a food natural toxicant is the discovery, made with the aid of GC-MS, ESI LC-MS, and LC-MS/MS, that the genotoxic carcinogen acrylamide is formed during some cooking processes.

### Anthropogenic Toxicants

Many examples of mass spectrometric methods for determining toxic or potentially deleterious anthropogenic compounds in foods can be found in the scientific literature. The range of compounds analyzed is wide and includes dioxins, polyaromatic hydrocarbons, pesticide and veterinary drug residues, plasticizers from packaging materials, and environmental contaminants. LC-MS, MS/MS, GC-MS, and GC-MS/MS techniques are used widely for determining these compounds down to parts per billion or even parts per trillion levels. For example, polar organophosphorus pesticides can be quantified by LC-MS/MS down to levels of  $0.01 \text{ mg kg}^{-1}$  in fruits and vegetables and dioxins are regularly determined in food matrices at femtogram levels.

Isotope dilution mass spectrometry is an accurate and sensitive technique for determining toxic trace elements in food matrices. Lead, cadmium, and thallium have been analyzed rapidly down to very low levels by ICP-MS. The latter technique is particularly useful for simultaneous measurement of a wide range of elements. Because the toxicity of an element can be highly dependent on its chemical form, ICP-MS is also useful in the speciation of toxic minerals in foodstuffs by combination with HPLC or SEC.

### Future Trends

Enormous advances in the scope and sensitivity of mass spectrometric techniques have occurred in the last decade. The use of modern techniques of organic MS, particularly APCI and ESI LC-MS, CE/MS, and MS/MS, has grown apace in the food and nutritional sciences. Applications of MALDI-TOF in the food sciences are also increasing, although at a lower rate (the frequent need for chromatographic separation in food-related applications has led to an understandable bias toward LC-MS methods).

The importance of ICP-MS in multielement analysis of foodstuffs is already well established, as is the use of this technique in human metabolic studies. Both types of application are being augmented by increased applications of combined chromatography/ICP-MS for conducting speciation studies. The advent of a new generation of high-precision isotope ratio ICP-MS instruments also opens up the exciting possibility of conducting metabolic studies without using enriched labels, by observing isotopic fractionation between different body compartments. High-precision ICP-MS also has considerable potential in food authentication (by linking isotopic composition to geographical origin, for example).

Fundamental studies of the metabolism of proteins, fats, and starches by GIR-MS are increasing and it is anticipated that practical applications to the metabolism of extrinsically labeled foods will make an impact in the future.

Mass spectrometry has a central role in the postgenomic science of proteomics, the qualitative and quantitative comparison of the entire protein complement of a genome under different conditions. The new science of metabolomics, the global, quantitative analysis of all the low and intermediate molecular weight metabolites expressed by a genome under specific conditions, has obvious applications in food science, for example, in assessing the safety of transgenic plants or in studying environmental effects on food poisoning microorganisms and mass spectrometry is one of the pivotal analytical techniques in metabolomics. This type of application is expected to increase in the future.

## Introduction

Forensic science is the application of science to problems encountered in the courts of law. Forensic laboratories specialize in the analysis, identification, and interpretation of physical evidence. Typically, analyses performed in such laboratories are concerned with determining (1) component identification of a sample, (2) quantitation or purity of sample components, or (3) similarities or differences between two or more samples. With automated instrumentation widely available, highly specific mass spectrometry (MS)-based technologies are now the most valuable tools used to achieve these desired analytical goals.

MS-based techniques, in the forensic setting, are primarily used for the identification of specific components in drug-related samples. These samples may contain drugs in dosage forms or in biological matrices. The drugs analyzed may be abused by the general population, a specific age group, or those used as performance enhancers in human or animal

sporting events. MS-based methodologies are also routinely used for the analysis of materials related to arson, explosives, and synthetic polymers. Applications in the characterization of inorganic elements for forensic science purposes have also been reported.

Most MS applications utilize electron ionization (EI) or chemical ionization (CI), a quadrupole analyzer, and a gas chromatograph (GC) as the sample introduction device. However, other MS methodologies such as tandem MS (MS/MS) and isotope-ratio are becoming more common. Recent advances in sample evaporation/ionization, high-mass ion resolution, and liquid chromatography (LC)–MS interfacing technologies have significantly expanded the potential forensic applications of MS-based approaches to the analysis of biomolecules, i.e., proteomics.

## Applications Resulting from Advances in Ionization and Ion Resolution Technologies

With recent advances in matrix assisted laser desorption/ionization (MALDI) and electrospray LC–MS interface technologies (awarded the 2002 Nobel prize in chemistry), MS can now be successfully applied to the analysis of compounds with high molecular weights or polar functional groups. Time-of-flight (TOF) MS is typically used to resolve and

### Introduction

Forensic science is the application of science to problems encountered in the courts of law. Forensic laboratories specialize in the analysis, identification, and interpretation of physical evidence. Typically, analyses performed in such laboratories are concerned with determining (1) component identification of a sample, (2) quantitation or purity of sample components, or (3) similarities or differences between two or more samples. With automated instrumentation widely available, highly specific mass spectrometry (MS)-based technologies are now the most valuable tools used to achieve these desired analytical goals.

MS-based techniques, in the forensic setting, are primarily used for the identification of specific components in drug-related samples. These samples may contain drugs in dosage forms or in biological matrices. The drugs analyzed may be abused by the general population, a specific age group, or those used as performance enhancers in human or animal

sporting events. MS-based methodologies are also routinely used for the analysis of materials related to arson, explosives, and synthetic polymers. Applications in the characterization of inorganic elements for forensic science purposes have also been reported.

Most MS applications utilize electron ionization (EI) or chemical ionization (CI), a quadrupole analyzer, and a gas chromatograph (GC) as the sample introduction device. However, other MS methodologies such as tandem MS (MS/MS) and isotope-ratio are becoming more common. Recent advances in sample evaporation/ionization, high-mass ion resolution, and liquid chromatography (LC)–MS interfacing technologies have significantly expanded the potential forensic applications of MS-based approaches to the analysis of biomolecules, i.e., proteomics.

### Applications Resulting from Advances in Ionization and Ion Resolution Technologies

With recent advances in matrix assisted laser desorption/ionization (MALDI) and electrospray LC–MS interface technologies (awarded the 2002 Nobel prize in chemistry), MS can now be successfully applied to the analysis of compounds with high molecular weights or polar functional groups. Time-of-flight (TOF) MS is typically used to resolve and

identify ions produced by MALDI, while conventional or tandem MS are used to identify LC eluates. While the analyzer in a tandem MS serves as a 'filter', the TOF detector collects all ions produced and is, therefore, theoretically more sensitive.

A recent report described MALDI-TOF MS characterization of ricin, an extremely potent poison from the seeds of the castor bean plant. Ricin has been mentioned in terrorism literature and was reportedly used in a high profile international spy homicide case. In the MS application, samples were first purified by LC fractionation or molecular weight cutoff filtration. Confirmation was carried out by comparing the MALDI-TOF MS spectrum of the tryptic digest against a standard and GC-MS identification of an alkaloid marker, ricinine.

In another forensic science application, electrospray LC-MS was used to determine elevated levels of insulin-like growth factor 1 (IGF-1) in serum as an indication of growth hormone (GH, somatotropin) abuse in racehorses. Structural identity of IGF-1 was confirmed by LC-MS and LC-MS/MS characterization of the endoproteinase Asp-N digestion product.

With improved interface technology, LC-MS is now commonly advocated for the analysis of smaller molecules with polar functional groups, especially drug metabolites and their conjugates. This approach can provide intact conjugate information not obtainable using parallel GC-MS approaches. It also bypasses the hydrolysis and chemical derivatization steps that are often required in GC-MS applications. The application of LC-MS to small, polar metabolites is exemplified in current studies investigating differential serotonin metabolism as a tool to differentiate between ethanol ingestion and postmortem ethanol formation in human specimens.

## Drug Analysis Using MS

Drug-related samples commonly encountered in forensic science laboratories may be present in dosage forms with varying degrees of purity, in plant materials or in biological matrices. Conventional EI-MS techniques are widely used to identify drugs in relatively pure forms, made possible either by prior purification procedures or via the use of a chromatographic device for sample introduction. CI techniques are also commonly employed to provide molecular weight information and occasionally to probe the number and the nature of active hydrogens attached to heteroatoms in the drugs of concern. Special chemical derivatizations in conjunction with GC-MS are effective in characterizing structural features of optical isomers of certain drugs, thus making possible their identification.

The use of an MS as the detector significantly improves the quantitative determination of drugs and their metabolites in biological matrices by making possible the use of isotope-labeled analogs (ILAs) of the analytes as internal standards (ISs). The most commonly employed ILAs are deuterated analogs. However, some studies have indicated that  $^{13}\text{C}$ -analogs may be more appropriate. Examples of these applications are presented below.

### Identification of Drugs and Drug Metabolite Using MS

Drug identifications are commonly carried out using both EI and CI MS. The most common applications involve the generation of a spectrum of the compound in question, similar to those shown in **Figure 1**, followed by a comparison against an authentic drug standard spectrum. An authentic spectrum can be obtained from a drug standard itself or retrieved from a library database. Useful compilations of mass spectra are given in the Further reading section.

Since authentic spectra are not always available, skillful and cautious interpretation of EI spectra can aid in the identification of an unknown compound. Mass spectrum interpretation of ephedrine-related compounds serves as an interesting example. Ephedrine and norephedrine derivatized with *N*-tri-fluoroacetyl-L-prolyl chloride (L-TPC) undergo an interesting migration/cleavage process (path A in **Figure 2**) in addition to the common ' $\beta$ -fission' process (path B in **Figure 2**), where the location of fragmentation is ' $\beta$ ' to the amino function and to the aromatic system. Path A is more favorable for norephedrine than for ephedrine as a result of the steric effect of ephedrine's methyl group. Path A is hindered if the hydroxyl hydrogen on norephedrine is replaced with a bulky addition such as the trimethylsilyl (TMS) group.

Chemical ionization MS, with various deuterated reagent gases, has been used to probe the number and nature of active hydrogens in a molecule. For example, based on the mass shifts of the 'protonated' ions that are observed when switching from ammonia ( $\text{NH}_3$ ) to deuterated ammonia ( $\text{ND}_3$ ), the number of active hydrogens in morphine and several other drugs have been demonstrated.

The total number of active hydrogens in a compound is derived from the observed mass shifts ( $n$ ) of the 'protonated' ion when  $\text{NH}_3$  is replaced with  $\text{ND}_3$  as the reagent gas:

$$n = M_{\text{ND}_3} - M_{\text{NH}_3} - 1$$

where  $M_{\text{ND}_3}$  and  $M_{\text{NH}_3}$  are the mass to charge ratios of the 'protonated' ions observed with  $\text{ND}_3$  and  $\text{NH}_3$  as the reagent gases, respectively.

**Figure 1** Comparison of the EI mass spectra of amphetamine (A) and L-TPC derivatized amphetamine (B). (Reproduced with permission from Liu RH (1989) Applications of mass spectrometry to forensic sciences. In: Lee HC and Gaensslen RE (eds.) *Advances in Forensic Science*, vol. 2 – Instrumental Analysis, p. 75. Year Book Medical Publications: Chicago, IL.)

**Figure 2** Electron impact fragmentation pathways of ephedrine-related compounds. (Reproduced with permission from Gadzala DE, Liu RH, Legendre MG, and Ku WW (1988) Mass spectra of derivatized ephedrine and norephedrine. *Organic Mass Spectrometry* 23, 851–852.)

The combined information provided by (1) mass shifts, (2) the tendencies of the protonated and adduct ions to lose molecules of water, and (3) the intensity ratio of adduct ion to protonated ion, may further reveal the nature of the active hydrogens involved, particularly in differentiating a phenolic from an alcoholic hydrogen.

### Chemical Derivatization in MS

Chemical derivatization of drugs is commonly employed when conducting GC–MS analysis. In

addition to improving chromatographic and stability characteristics of the analytes, derivatized drugs may also produce characteristic mass spectra that are not available from parent compounds; thereby, better achieving the desired analytical objectives. Derivatization approaches also form the basis for optical isomer differentiations.

The detection limit and quantitation of compounds may be improved by derivatization, yielding intense high-mass ions not available from the parent compounds. In general, for any given compound the higher the mass of the ion monitored, the lower the

background noise. For example, the spectrum of amphetamine (**Figure 1A**) exhibits low intensities of ions at higher mass range, while L-TPC derivatized amphetamine shows significant ion intensity at  $m/z$  237. Considering the probability of contributions from interfering analytes, the base peak from un-derivatized amphetamine,  $m/z$  44, is not suitable for quantitative purposes and thus, requires derivatization.

Detection limits can also be improved through the introduction of elements of high electron affinities into the compound and the monitoring of negative ions using negative CI-MS. This approach has been successfully applied in the analysis of cannabinoids in biological samples. Following derivatization with pentafluoropropionic anhydride (PFPA),  $\Delta^1$ -tetrahydrocannabinol has been quantitatively reported in the mid-pg/ml range in postmortem blood.

Mass shifts in the spectra produced by different derivatizing agents may provide extremely useful information for the elucidation of certain structures. For example, the number of TMS groups attached to the parent compound can often be deduced by observing the mass shifts that occur upon replacing *N,O*-bis-(trimethylsilyl)-acetamide (BSA) with  $d_9$ -BSA as the derivatizing agent. This information facilitates the identification of desoxymorphine-A,

monoacetyldesoxy-morphine-A, and diacetyldesoxy-morphine-A as the impurities in an illicit heroin sample. The same approach is used to characterize  $O^6$ - and  $O^3$ -acetylmorphine. Similarly, the 28-amu mass shift observed in the mass spectrum of derivatized secobarbital indicates the replacement of two hydrogen atoms by two methyl groups (**Figures 3A** and **3B**).

Proper selection of derivatizing agents can also help determine the molecular weight of a compound. Compared to parent compounds, TMS derivatives of *N*-substituted barbiturates are found to generate less olefin radical elimination ( $[M-41]^+$  and  $[M-55]^+$ ). Instead, the formation of the  $[M-15]^+$  ion is favored, making it easier to recognize the molecular weight of the compound under examination.

MS is generally ineffective in differentiating enantiomers by itself; however, MS can be made effective by the proper derivatization of enantiomers followed by chromatographic separation. Although chiral stationary phases are available for direct separation of enantiomers, derivatization with chiral or achiral agents can often improve chromatographic characteristics. As an example, the total ion chromatograms of the L-TPC-derivatized amphetamine and methamphetamine are shown in **Figure 4**. The

**Figure 3** Mass spectra and chemical structures of pentobarbital (A) and methyl derivative of pentobarbital (B). (Reproduced with permission from Liu RH and Gadzala DE (1997) *Handbook of Drug Analysis – Applications in Forensic and Clinical Laboratories*, p. 225. Washington, DC: American Chemical Society.)

**Figure 4** Total ion chromatograms of L-TPC derivatized amphetamine (A), methamphetamine (B), and amphetamine and methamphetamine mixture (C). (A) and (B) are obtained from a 25 m (0.30 mm ID) glass capillary Chirasil-Val column; (C) is obtained from a 25 m (0.20 mm ID) fused silica glass capillary SP-2100 column. La, L-amphetamine; Da, D-amphetamine; Lm, L-methamphetamine; Dm, D-methamphetamine; l, L-TPC; and d, D-TPC. (Reproduced with permission from Liu RH (1981) *Approaches to Drug Sample Differentiation*, p. 32. Taiwan: Central Police College Press.)

four possible isomers resulting from the reaction of D- and L-amphetamine with D- and L-TPC are completely resolved by the Chirasil-Val column (Figure 4A). The methamphetamine counterparts are resolved into three peaks (Figure 4B). Since the achiral column (SP-2100) cannot resolve enantiomers, only two peaks are observed (Figure 4C).

### ILAs as ISs

The use of MS-based methodologies for quantitative analysis is now a routine practice in forensic science laboratories. In most applications, ILAs of the analytes are used as the ISs, and the MS is operated in the selected ion monitoring (SIM) mode. Although  $^2\text{H}$ -analogs are the most commonly used ILAs, recent comparative studies have suggested that  $^{13}\text{C}$ -analogs (Figures 5A–5C) could be more effective. With virtually identical chemical properties and MS fragmentation characteristics, an ILA is a preferred IS because it offers the following advantages.

1. Errors derived from incomplete recovery of the analyte in the sample preparation process and/or varying GC and MS conditions are compensated for.
2. The presence of interfering materials (or mechanisms) which affect the detection or quantitation of the analyte will result in an altered response and ion intensity ratios or the absence of the IS in the final chromatogram; thus, alerting the analyst to conduct further investigation.

Before an ILA of the analyte is adopted as the IS, several important parameters should be carefully considered.

1. The ILA should be labeled with a sufficient number of atoms of a selected isotope so that the corresponding ions selected from the IS and analyte possess a significant mass difference. This is especially critical when sulfur atoms are present or a trimethylsilyl derivative is used.
2. The ILA should be manufactured with extremely high isotopic purity. Otherwise, the addition of the IS may result in the appearance of a significant amount of the analyte in a true negative sample and may also introduce errors in quantitation.
3. The labeling isotopes must be positioned at appropriate locations in the molecular framework of the compounds so that, after the fragmentation process, a sufficient number of high-mass ions, retaining the labeling isotopes, are present with significant intensities. Furthermore, these ions should not contribute to the intensities of the corresponding ions derived from the nonlabeled analyte. These ions and their counterparts in the analyte may then be monitored for ion ratio evaluation to facilitate qualitative compound identifications and quantitative determinations.

In order to establish a linear calibration curve, the intensities of the ions designated for the analyte and the IS must not have cross-contribution. For example, in a secobarbital/ $^{13}\text{C}_4$ -secobarbital study, calibration curves were evaluated using two pairs of ions:  $m/z$  196/200 and 181/185 (Figures 5A and 5C). For  $m/z$  196 (designed for the analyte), 0.23% of the measured intensity is contributed by the IS, while 0.017% of the measured intensity of  $m/z$  200 (designed for the IS) is contributed by the analyte. On the other hand, 1.6% of the measured intensity of  $m/z$  181 (designed for analyte) is contributed by the IS, while 0.29% of the measured intensity of  $m/z$  185 (designed for the IS) is contributed by the analyte. Figure 6 clearly demonstrates the difference in linearity of the calibration curves established by these two ion pairs. When cross-contribution occurs, non-linear models can best describe the observed data and should be seriously considered.

**Figure 5** Mass spectra and chemical structures of secobarbital (A),  $^2\text{H}_5$ -secobarbital (B), and  $^{13}\text{C}_4$ -secobarbital (C) (All as methyl-derivatives). (Reproduced with permission from Chang W-T, Smith J, and Liu RH (2002) Isotopic analogues as internal standards for quantitative GC/MS analysis – molecular abundance and retention time difference as interference factors. *Journal of Forensic Sciences* 47: 873–881.)

## Analysis of Nondrug Samples of Forensic Science Interest

MS in conjunction with GC is commonly employed during fire investigations. The GC–MS is capable of determining whether an observed hydrocarbon chromatogram pattern is derived from an accelerant or from pyrolysis products of various polymers. If the chromatogram is indicative of an accelerant, GC–MS is able to characterize what category of accelerant was present. Additionally, MS has been used to identify explosives and their postblast residues.

Distinct ion chromatograms are observed from debris derived from fire accelerant and those resulting from the pyrolysis of various polymers. Selected ions representing the following categories of

compounds are used to display the distributions of these compounds in a chromatogram: aliphatics ( $m/z$ : 57, 71, 85, 99), alicyclics ( $m/z$ : 55, 69, 83, 97), alkylbenzenes ( $m/z$ : 91, 105, 119, 183), alkylstyrenes ( $m/z$ : 104, 116, 132, 146), naphthalenes ( $m/z$ : 128, 142, 156, 170), terpenes ( $m/z$ : 93, 121, 136), biphenyls ( $m/z$ : 154, 168, 182, 196), and polynuclear aromatics ( $m/z$ : 178, 192, 206).

Common fire accelerants show distinct ion chromatogram profiles of alkylbenzenes and alkyl-naphthalenes. High percentages of these compounds are present in evaporated gasoline. Aviation fuel contains low-boiling alkylbenzenes similar to gasoline, but lacks significant quantities of high-boiling alkylbenzenes and alkyl-naphthalenes. Fuel oil and diesel fuel have a boiling range similar to that of evaporated gasoline, but are deficient in aromatics. Charcoal

**Figure 6** Linear and hyperbolic calibration results using ion-pairs with different degrees of cross-contribution – Secobarbital (SB)/ $^{13}\text{C}_4$ -secobarbital ( $^{13}\text{C}_4$ -SB):  $m/z$  196/200, 181/185. A total of 0.23% of the measured intensity of  $m/z$  196 (designed for SB) is contributed by  $^{13}\text{C}_4$ -SB; while 0.017% of the measured intensity of  $m/z$  200 (designed for  $^{13}\text{C}_4$ -SB) is contributed by SB. A total of 1.6% of the measured intensity of  $m/z$  181 (designed for SB) is contributed by  $^{13}\text{C}_4$ -SB, while 0.29% of the measured intensity of  $m/z$  185 (designed for  $^{13}\text{C}_4$ -SB) is contributed by SB. (Reproduced with permission from Liu RH, Lin T-L, Chang W-T, *et al.* (2002) Isotopically labeled analogues for drug quantitation. *Analytical Chemistry* 74: 618A–626A.)

lighter fluid and low-boiling naphthas are devoid of aromatic hydrocarbons. Paint thinners have significant amounts of middle-boiling alkylbenzenes, but few alkyl-naphthalenes.

In the forensic science laboratory, thermogravimetry and pyrolysis techniques are often combined with MS for the analysis of fiber and paint. Limited MS studies conducted on nylons, polyesters, acrylics, polyolefins, chlorine-containing polymers, cellulose, and various natural fibers concluded that it may be possible to differentiate some of these materials. However, MS techniques do not generally provide the overall discrimination power that has been demonstrated by IR-based methodologies.

A substantial number of studies on the characterization of vehicle paints, mainly alkyd and acrylic resins, have been reported. Alkyd resins, which are complex polyesters formed by co-polymerizing phthalic anhydride, polyols, and saturated and unsaturated fatty acids, can usually be classified with MS techniques on the basis of hydrocarbon chain length and modification components such as melamine. Characterizations of acrylic resins are based on CI MS analysis of monomers that are reasonably reproducible by pyrolysis techniques.

Mass spectrometric characteristics of common explosive substances, such as nitrate esters, nitramines, and nitroaromatic compounds, have been studied with the intention of developing effective approaches and protocols for preventive detection of hidden explosives and the analysis of postexplosion residues in debris materials. It has been strongly advocated that the analysis of explosives should follow the same criteria applied to drugs, i.e., MS identification regardless of how many other chromatographic techniques have been applied. Using GC–MS in the EI and negative CI mode, ethylene glycol dinitrate (EGDN), nitroglycerine (GTN), 2,4,6-trinitrotoluene (TNT), and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) can be identified at the picogram to low nanogram level. The identification of GTN, TNT, PETN, RDX, and tetryl (2,4,6-trinitrophenolmethyl-nitramine) in postblast residue by GC–MS have also been reported. The development of portable MS configurations for detecting vapors of hidden explosives is an area that attracts much interest and may provide valuable service in the future.

## Tandem MS in Forensic Science

Earlier applications of tandem MS methods included the determination of the exact structure of ‘China White’ ( $\alpha$ -methylfentanyl) and the screening and confirmation of multiple drugs in biological fluids. The exact structure of  $\alpha$ -methylfentanyl was pieced together through successive pairing of EI ‘complementary ions’, whose sum of masses equals that of the molecular ion, and the determination of the structures of these paired ions by their collisionally induced dissociation spectra, i.e., MS/MS spectra.

Tandem MS procedures have been employed for the rapid screening and confirmation of up to 50 drugs in a single sample, at drug levels of nanograms per milliliter to micrograms per milliliter. In this screening method, the molecular ion is selected by the first MS stage, followed by collisionally induced dissociation, which produces daughter fragments that are then analyzed by the second stage of the MS. Such a procedure involves the use of (1) selected reaction monitoring for preliminary screening of possible drugs, (2) neutral loss screening to indicate the presence of any member of a given class of drugs, and (3) the acquisition of complete daughter spectra for confirmation. Using the first stage MS to isolate a specific ion, not only saves time, but also significantly improves the limits of detection by reducing chemical noise in the MS/MS spectrum.

Applications of GC–MS/MS and LC–MS/MS by forensic scientists are now frequently reported. For

example, a recent report on the analysis of accelerants in fire debris demonstrates that information derived from a GC coupled with ion trap MS/MS can greatly reduce interference caused by pyrolysis of construction and furnishing materials. Another example is the confirmation and quantitation of sildenafil and its metabolite using LC-MS/MS in post-mortem tissues and fluids at levels down to 1 ng per g and 1 ng per ml, respectively. By removing the majority of interfering clutter in the first stage of MS, the MS/MS spectrum generated is extremely clean. Thus, both detectability and specificity are increased with MS/MS.

## Stable Isotope Ratio MS

Under certain circumstances standard MS techniques are unable to elucidate the necessary results. For example, sample comparisons based simply on compound identification and quantitation can be misleading if sample doping has occurred. Additionally, determining the regional origin of plant-derived drugs has been a difficult, if not impossible task. An approach that has proven successful in achieving these investigative goals is the comparison of naturally occurring isotope compositions in the samples of concern. The most convenient isotope to measure is the  $^{13}\text{C}$ -enrichment level.

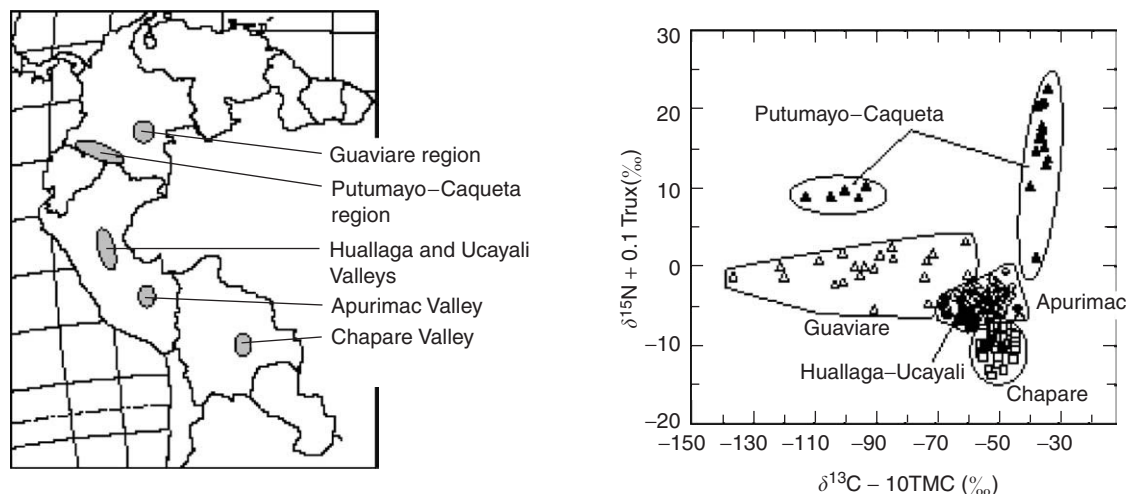

Differences in  $^{13}\text{C}$ -enrichment level are universally expressed using the delta notation shown below:

$$\delta^{13}\text{C}(\text{‰}) = \left[ \frac{R_{\text{sample}}}{R_{\text{standard}}} - 1 \right] \times 1000$$

where  $R$  is the ratio of the number of atoms of the minor isotope to that of the major isotope. In order

to compare isotope enrichment levels, a standard reference material is needed. The  $^{13}\text{C}$ -enrichment level found in Pee Dee belemnite (PDB), i.e., a calcium carbonate deposit of the fossil *Belemnitella americana* from the Peedee formation in South Carolina, is used as the reference.

The determination of  $^{13}\text{C}$ -content has recently become a major area of interest in the antidoping testing community. This interest is derived from the desire to develop a subjective parameter for detecting misuse of androgens, especially testosterone. Since testosterone concentration varies among individuals, the testosterone/epitestosterone, i.e., the  $17\alpha$  epimer and metabolite of testosterone, ratio was used as an indirect marker of testosterone administration. However, this approach has been circumvented through doping oneself with epitestosterone. By determining the androgen  $^{13}\text{C}$ -content during the testing process, differentiation between endogenous and synthetic testosterone and epitestosterone can be achieved. This procedure is considered the most effective approach in identifying androgen doping. Its effectiveness is based on the fact that synthetic androgens are generally made from a single plant species, which have lower  $^{13}\text{C}$ -contents than those derived from endogenous sources. For example, it has been reported that the  $\delta^{13}\text{C}$  values for all four synthetic epitestosterones examined were  $\leq -30.3\text{‰}$ , while the mean  $\delta^{13}\text{C}$  value of epitestosterone obtained from 43 healthy male urine samples was  $-23.8\text{‰}$  (SD,  $0.93\text{‰}$ ). Nine of 10 athletes' urine samples, with epitestosterone concentrations  $>180\text{ }\mu\text{g l}^{-1}$ , had  $\delta^{13}\text{C}$  values within  $\pm 3$  SD of the control group. The other athlete's  $\delta^{13}\text{C}$  value was  $-32.6\text{‰}$  and was suggested to have administered synthetic epitestosterone.

**Figure 8** Constructed based on data reported in Desage M, Guillury R, Brazier JL, *et al.* (1991) Gas chromatography with mass spectrometry or isotope-ratio mass spectrometry in studying the geographical origin of heroin. *Analytica Chimica Acta* 247: 249–254.

This isotope approach has also been very successful in differentiating between beet sugar and cane sugar, due to differences of carbon fixation pathways of these two plants. Additionally, it has been used to detect the addition of sugar to honey and natural fruit products. Typically, the  $\delta^{13}\text{C}$  value for cane sugar is  $-11.5\text{‰}$ , while most fruit sugars are lower than  $-20\text{‰}$ .

$^{13}\text{C}$ -enrichment levels have been successfully applied to samples in the field of forensic science. Coca leaves from South America were found to vary in their  $\delta^{13}\text{C}$  ( $-32.4\text{‰}$  to  $-25.3\text{‰}$ ) and  $\delta^{15}\text{N}$  ( $0.1$ – $13.0\text{‰}$ ) values. Humidity levels and the length of the rainy season, and differences in soils were thought to affect the fixation processes and cause the observed

subtle variations in  $^{13}\text{C}$  and  $^{15}\text{N}$  contents, respectively. In conjunction with the variations of trace alkaloids (truxilline and trimethoxycocaine) found in cocaine, researchers were able to correctly identify 96% of 200 cocaine samples originating from the regions studied (Figure 7). Additionally, the  $^{13}\text{C}$ -enrichment levels in heroin samples derived from various geographic regions have been investigated. Reported data are converted into a graphical presentation by this author (Figure 8).

Sample differentiation approaches based on  $^{13}\text{C}$ -enrichment levels have also been advocated as a basis for a potential sample tagging mechanism. An exploratory study utilized different percentages of  $^{13}\text{C}$ -enriched N-methylamine during the methamphetamine synthesis process. Data shown in Table 1, obtained using a general purpose GC–MS system, indicate that a variation step of 0.25% in  $^{13}\text{C}$ -N-methylamine was sufficient for product differentiation. It was estimated that the variation step could be reduced by a factor of 50-fold if an isotope ratio mass spectrometer was used.

### Introduction

Mass spectrometry has become established as a very powerful method of gas analysis, being fast, accurate, multicomponent, and flexible. During the past two decades, advances in technology have enabled mass spectrometers to be designed specifically for continuous or fast online compositional measurement of gases to facilitate industrial plant process control or for environmental monitoring. Modern instruments are typically compact, robust, very reliable, and simple to use with flexible user-friendly software. They are often equipped with multistream sampling devices, to measure samples from many sample points with high frequency, to benefit from the speed of analysis. Gas analysis mass spectrometers can be configured with suitable protection for operation in hazardous areas in industrial plants.

### Instrumentation

The sample of a gas analysis mass spectrometer usually passes through an enclosed electron ionization

(EI) ion source, in which the ionization volume is operated at a pressure of typically  $10^{-4}$  mbar, which is higher than that of the mass analyzer and the thermionic filament. This gives improved detection limits, since the effect of background pressure in the analyzer is reduced. Interaction between the hot filament and the sample is minimized; this might otherwise give rise to artifact peaks or, in the case of reactive gases, changes in the sensitivity of the instrument.

The process of ionization of an EI source typically produces fragment ions and multiply-charged ions as well as molecular ions. Additionally the existence of isotopes produces ions having different masses. The relative numbers of ions formed at different  $m/z$  from a given gas component, known as the ‘fragmentation pattern’ or ‘cracking pattern’, is used for identification and quantification. The fragmentation pattern can be influenced by instrumental factors such as the energy of the bombarding electrons, temperature, the geometry of the ion source, mass spectrometer lens voltages, pressure, mass analyzer type and geometry, and detector type. To facilitate comparison, reference data on fragmentation patterns usually originate from measurements using 70 eV electrons and at a source pressure of  $10^{-4}$  mbar or lower. Under these conditions, an analytical mass spectrometer

### Introduction

Mass spectrometry has become established as a very powerful method of gas analysis, being fast, accurate, multicomponent, and flexible. During the past two decades, advances in technology have enabled mass spectrometers to be designed specifically for continuous or fast online compositional measurement of gases to facilitate industrial plant process control or for environmental monitoring. Modern instruments are typically compact, robust, very reliable, and simple to use with flexible user-friendly software. They are often equipped with multistream sampling devices, to measure samples from many sample points with high frequency, to benefit from the speed of analysis. Gas analysis mass spectrometers can be configured with suitable protection for operation in hazardous areas in industrial plants.

### Instrumentation

The sample of a gas analysis mass spectrometer usually passes through an enclosed electron ionization

(EI) ion source, in which the ionization volume is operated at a pressure of typically  $10^{-4}$  mbar, which is higher than that of the mass analyzer and the thermionic filament. This gives improved detection limits, since the effect of background pressure in the analyzer is reduced. Interaction between the hot filament and the sample is minimized; this might otherwise give rise to artifact peaks or, in the case of reactive gases, changes in the sensitivity of the instrument.

The process of ionization of an EI source typically produces fragment ions and multiply-charged ions as well as molecular ions. Additionally the existence of isotopes produces ions having different masses. The relative numbers of ions formed at different  $m/z$  from a given gas component, known as the ‘fragmentation pattern’ or ‘cracking pattern’, is used for identification and quantification. The fragmentation pattern can be influenced by instrumental factors such as the energy of the bombarding electrons, temperature, the geometry of the ion source, mass spectrometer lens voltages, pressure, mass analyzer type and geometry, and detector type. To facilitate comparison, reference data on fragmentation patterns usually originate from measurements using 70 eV electrons and at a source pressure of  $10^{-4}$  mbar or lower. Under these conditions, an analytical mass spectrometer

will typically display fragmentation patterns consistent with library data to within perhaps  $\pm 30\%$  relative.

Other ionization techniques are sometimes used, such as atmospheric pressure ionization (API), photoionization, and chemical ionization. Of these, API has been the most widely applied, and involves the production of ions at high pressure in a corona discharge. The ions are then swept by the bulk gas flow into a region where they are extracted by lens voltages into the vacuum part of the mass spectrometer for mass separation and detection.

There are many types of mass analyzers for gas analysis, but the magnetic sector and the quadrupole are the most widely used, with time-of-flight, Fourier transform ion cyclotron resonance, and ion trap types being advantageous for special applications, for example, those requiring very fast measurement, high resolution, and high sensitivity, respectively. Since mass spectrometers generally operate at a pressure of  $10^{-5}$  mbar or lower, they require a high vacuum system. In contrast, the sample will usually originate at close to atmospheric pressure (1000 mbar). It is therefore necessary to admit the sample into a high-vacuum environment, in a way which reduces the sample pressure by many decades. During this transfer the composition must remain sufficiently consistent for the analysis in hand.

After passing through the mass analyzer, the ions impinge directly onto a Faraday electrode or, for enhanced sensitivity, a secondary electron multiplier. The typical range of ion currents measured are  $10^{-18}$ – $10^{-9}$  A. Almost invariably, a computer will record, process, and display the data. In principle, quite complex calculations may be executed by the computer to derive the compositional results required, but the physical phenomena involved are essentially linear, so well-established algorithms are generally employed.

## Gas Analysis by Mass Spectrometry

In order to perform an analysis, one must establish a correlation between the molecular species present and the peaks observed in the mass spectrum. The gas may consist of known components, whose relative concentrations are to be determined, or alternatively it may be required to identify unknown species.

If the species are known, the first step is to identify suitable mass peaks to monitor. 'Standard' tabulations of mass spectra are readily available. For example, consider the analysis of breathable air. The main species of interest are nitrogen, oxygen, argon,

and carbon dioxide. **Table 1** shows standard spectra for these four gases. It is conventional to normalize each spectrum to the base peak (that is, the most intense). (It should be mentioned again that these values are not fixed and vary from instrument to instrument and depend on actual operating parameters and also may change with time.)

One then identifies peaks that will permit analysis of each individual species, if possible avoiding or minimizing overlaps between the spectra. In the present example, the base peaks for each of the four species are suitable since the amount of carbon dioxide is sufficiently low so that the overlap or 'interference' with nitrogen at mass 28 is small. This overlap is easily corrected for by simple subtraction if the ratio of peaks from carbon dioxide is determined by calibration with a suitable gas containing carbon dioxide. For some gas analysis applications, there is considerable overlap and development of an analytical method then becomes more complex, involving a search for peaks which have less overlap but still have worthwhile intensity. The analysis of several overlapping or 'interfering' gas mixtures inevitably involves measurement by deconvolution of the overlapping peaks. An important assumption is made (and is generally obeyed) that the overlapping peaks when combined obey the principle of linear peak superposition. The principle of linear peak superposition is that the composite peak height at a particular mass is simply equal to the sum of the peak heights which correspond linearly to the individual concentrations of the contributing components in the complex mixture. This may be represented as follows:

$$i_1 = s_1 f_{11} c_1 + s_2 f_{21} c_2 + s_3 f_{31} c_3 + \dots + t s_n f_{n1} c_n$$

where  $i$  is a composite peak height, and for 1 to  $n$  components contributing to this peak,  $s$  is the base peak sensitivity,  $f$  its cracking pattern, and  $c$  its concentration. Values of  $s$  and  $f$  are determined for each component during calibration. During analysis, the peak heights ( $i$ ) are measured for 1 to  $n$  (or  $>n$ ) masses so that there are at least  $n$  simultaneous equations to determine the  $n$  unknown values of  $c$ . Matrix inversion is generally used to solve these sets of simultaneous equations. These calculations are normally executed easily and rapidly by a computer within a fraction of a second, and typically the complete analysis going from sample introduction to giving a reading of gas concentrations takes only seconds.

If calibration cannot be performed, then estimates can be made for values of  $f$  and  $c$  above, but subsequent errors may be considerable. The greater the overlap, the more serious is the possibility of error. Generally, for reliable quantitative work, complete calibration should be made. Even with calibration, errors can be significant due to changes in sensitivity and fragmentation patterns. There can be adverse influences from poor environmental control, ionizer instability, mass scale instability, and detector instability. There may also be unexpected errors from a number of phenomena such as tails from much larger peaks (an effect often referred to as 'abundance sensitivity'), nonlinearity in response, detector noise and drift, vacuum system out-gassing, permeation and other background phenomena (such as poor high vacuum pump compression for light gases), inaccurate or unstable calibration gases, memory, adsorption, reaction and conditioning effects, and generally poor sampling. Sometimes there can be interferences from unexpected components due to reactions occurring in the ion source to generate unexpected species (e.g., cracking of hydrocarbons to generate molecular hydrogen) which need to be considered. Where two or more components share very similar spectra, their quantification tends to become very inaccurate or impossible (e.g., *cis*- and *trans*-alkenes). However, despite these various possibilities for measurement error, a carefully installed and maintained mass spectrometer, with the analytical method correctly configured, is able to produce very accurate and reproducible analysis for a wide range of applications. Accuracy is typically better than 1% relative over 1 month with standard deviations over 24 h typically better than 0.1% relative.

When analyzing for unknown components, similar considerations apply, but of course with a different emphasis. An experienced operator will be able to identify individual gases from the measured spectrum, especially if only a few components are

present. If the mixture is complex, the measured signals can be compared with a library of 'standard' spectra, and a 'most likely' composition inferred. A linear least-squares calculation is typically used, but the error can be considerable, due to actual spectra sometimes being significantly different from the 'standard' spectra. It is, however, normally necessary, where the task is to reliably identify unknowns in a multicomponent mixture, that the system includes a gas chromatograph to provide a preseparation, to enable introduction of the components into the mass spectrometer one at a time, so that individual component mass spectra can be identified more easily in a sequential manner.

## Inlets

There are many ways of introducing a sample into a mass spectrometer. Those most commonly used for general gas analysis and vacuum work are discussed below. In order to describe these, it is first necessary to review some basic gas properties.

## Gas Properties

The physical properties of the sample gas, such as pressure, density, temperature, and flow rate are described by classical kinetic theory. Thus the ideal gas equation  $PV = nRT$  applies throughout the system. However, gas flow patterns change as the pressure is reduced, giving rise to effects that must be considered in the design of inlets.

The behavior of gas at high pressure is dominated by intermolecular collisions. Each molecule travels only a short distance, characterized by the mean-free-path (MFP) between collisions. The MFP can be estimated from kinetic theory, and is, for example,  $\sim 6.5 \times 10^{-5}$  m for nitrogen at atmospheric pressure. If a gas is contained in a vessel whose shortest dimension is much longer than the MFP, then only molecules close to the wall of the vessel interact with it directly. These considerations lead to the concept of gas viscosity, and the gas is said to undergo 'viscous' or 'laminar' flow. This is a bulk property of the gas, and the flow rate depends upon the difference in total pressure and upon the bulk viscosity. In the vacuum system, the MFP is usually longer than the dimensions of the containing vessel. Intermolecular collisions seldom occur, and collisions with the wall of the vessel dominate. The flow rate for each species then depends upon the difference in partial pressure for the individual species, and upon the molecular weight. This condition is called 'molecular flow'.

As the sample passes to the ionizer, the nature of the gas flow will alter from predominantly viscous flow at high pressure to molecular flow within the

ionizer. A consequent change in composition, known as 'fractionation', can be avoided by employing special inlet techniques.

Typically the ionizer is pumped at a rate of  $\sim 1 \text{ l s}^{-1}$ . Therefore a gas introduction rate of  $\sim 0.1 \mu\text{l s}^{-1}$ , is typically used to create a pressure in the ionizer of  $10^{-4}$  mbar.

### Capillary with By-Pass

A particularly versatile inlet for continuous online analysis is the 'capillary with by-pass'. This is shown schematically in **Figure 1**. The sample, initially at atmospheric pressure, passes down a length of narrow diameter tubing. The pressure reduces under viscous flow. At a location where the pressure has reduced to a suitable value (typically 10 mbar), a small fraction of the flow is diverted through a leak (a plug of sintered material or small orifice) into the mass spectrometer. The remainder of the flow passes on to a vacuum pump that maintains the flow. The gas flow is essentially viscous from the atmospheric pressure end of the tubing to past the location of the leak. At the leak, the pressure is low enough for the entire flow through the leak to be molecular. By this means, fractionation is avoided, and the relative concentrations of the components are the same in the ionizer as in the origin of the sample at atmospheric pressure. The inlet is thus suitable for applications where the gas composition will alter significantly. It is relatively tolerant of changes in sample pressure, and responds rapidly to changes in composition, since the flow down the capillary is rapid. Memory effects are minimized, especially if trace heating is employed.

### Membrane

A method of enhancing the response preferentially to trace organic compounds is with a membrane inlet. Typically a poly(dimethylsiloxane) membrane is used

as the interface between the sample at atmospheric pressure and the ionization chamber at  $10^{-4}$  mbar. The membrane inlet serves to provide (when the sample gas is air) approximately the same gas introduction rate as with the other types of inlets, but with a typically 10–100 $\times$  preferential transmission of organic compounds to give significantly improved trace detection.

An interesting variation of the membrane inlet is to use it as a sampling device for sampling dissolved organic gases in water by flowing a carrier gas through a capillary of poly(dimethylsiloxane) immersed in the water sample.

### Direct Capillary Inlet

A particularly compact and simple inlet consists of a short length of narrow-bore tubing. For example a 0.5 m length of 0.03 mm capillary provides  $\sim 0.1 \mu\text{l s}^{-1}$  flow rate. The gas flow changes from viscous to molecular flow as it passes through the constriction, resulting in fractionation of the sample. The relative concentrations in the ion source are inversely proportional to the square root of the molecular weights. For example with a gas sample of hydrogen and nitrogen, the relative concentrations will be altered by a factor of  $(28/2)^{0.5}$ , i.e., 3.7. Therefore, the hydrogen/nitrogen ratio will be 3.7 $\times$  less in the ionizer compared with the original sample. This means the response to lighter components is less favorable. The direct capillary inlet is easily blocked by particulates or condensation and may take several seconds to equilibrate when the gas composition alters.

A direct capillary inlet can be configured rapidly, and will often be considered for experimental work or if small dimensions are important; but it must be used with caution. The response is slow and mass dependent.

### Leak Valve

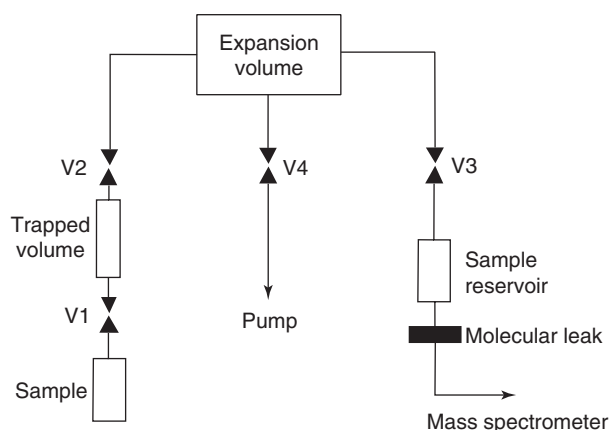

A leak valve gives capability over a wide range of pressures, and, if motorized, gives the possibility of automatic compensation for varying sample pressures. Fractionation effects are similar to those of the direct capillary inlet.

### Batch Inlet

A basic batch inlet is shown in **Figure 2**. A small quantity of gas is expanded into an evacuated volume, so that the pressure is low enough for molecular flow to occur in the leak to the mass spectrometer. No mixing of flow regimes occurs, so fractionation is absent. However, it involves more hardware than other inlets, and cannot give truly

**Figure 1** Schematic diagram of capillary inlet with by-pass.

**Figure 2** Schematic diagram of batch inlet.

continuous readings. Typically a batch inlet is employed for laboratory analysis of small samples, e.g., 1 mbar l of gas.

## Data Acquisition and Processing

A modern commercial mass spectrometer will incorporate a computer or will offer a facility to communicate with a computer via a data link, for example, to a plant control system using serial, ethernet or analog, and/or digital signals. This allows data to be stored and manipulated, often in 'real-time', so that results can be displayed to the user in a convenient form or to be utilized for process control either automatically via a closed loop or for operator 'fine-tuning'. A mass spectrum may be displayed as a continuous scan over a specified mass range similar to a strip-chart, but this is difficult to interpret, and is not directly quantitative.

It is usually preferable to monitor only a few selected masses, using computer control to switch between them. This simplifies the presentation of the data and allows much more rapid measurement. An alternative method is to measure every peak within a specified mass range. In either case, the rate of acquisition of data may be as high as several hundred separate measurements per second. Such high data rates are not always appropriate or convenient, so facilities will be provided to make measurements intermittently, or to accumulate averaged signals. Typically for precise quantitative gas analysis, each mass takes about 0.3–1 s to be measured. Most gas analysis mass spectrometers are designed to operate at low resolution (less than 100), so that peaks can be measured by peak jumping with infrequent mass calibration. Analysis stability and accuracy is dependent on a number of factors. By adopting a design of mass spectrometer which exhibits flat-topped peaks, such as with a magnetic sector instrument

(as seen in Figure 3) makes the system much more tolerant to errors in mass alignment due to drift, due to noise, temperature changes, or spurious surface potentials. Thereby, the peak height measurement reproducibility is enhanced and the analysis precision is improved.

## Calibration

In common with other analytical techniques, the best accuracy will be obtained by reference to calibrated gas mixtures whose composition is similar to that of the sample. This is straight forward if the sample composition remains fairly constant. If the gas composition varies more widely, one may need to calibrate by reference to a small number of selected gas mixtures. In a typical case, for a complete calibration, to provide accurate composition monitoring, it is necessary to use a minimum number  $N$  calibration gases where  $N$  is calculated as:

$$N = M + 2$$

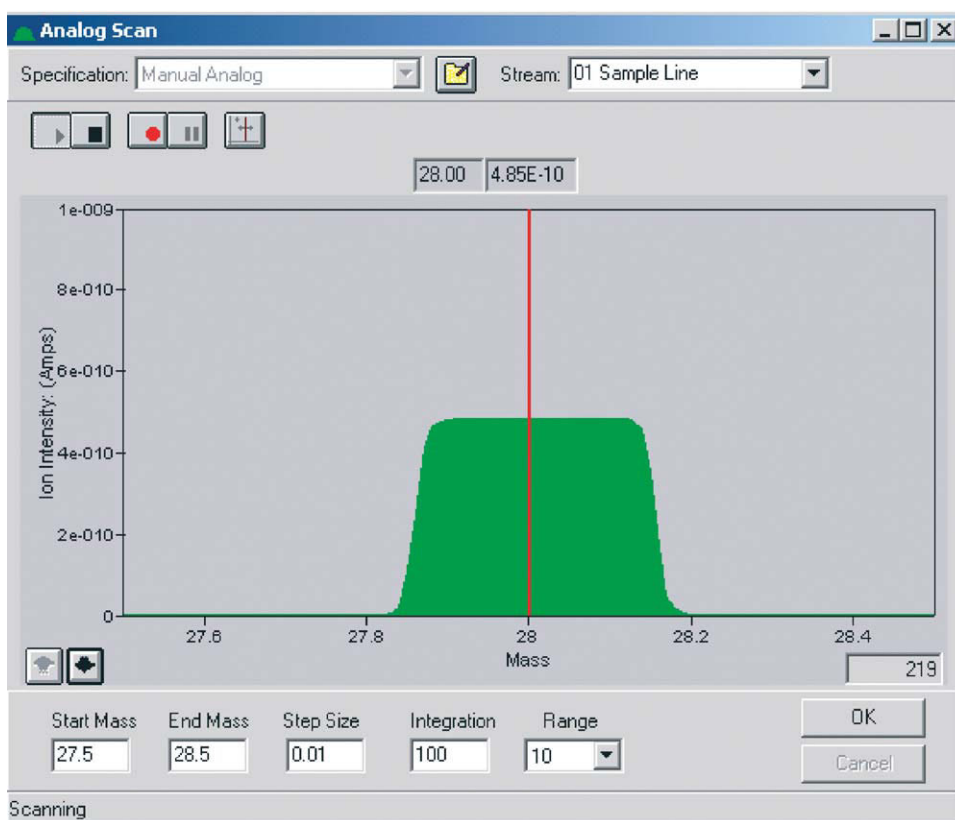

where  $M$  is the total number of components having fragmentation patterns that are used in the analysis.

The two additional calibration gases required are typically a multicomponent mixture to accurately determine the relative sensitivities and a 'background' gas for measuring the background signals at the various masses used in the analysis. As an example, consider the case of the reactor outlet gas from an ethylene oxide (EO) plant. Table 2 shows the components and their typical concentration levels, relative sensitivities, and fragmentation patterns. Note only a minimum set of masses has been considered for the analysis, i.e., the number of masses = the number of components = 8.

It is seen that there are five components having fragmentation patterns that are used, namely  $C_2H_4$ ,  $C_2H_6$ ,  $O_2$ , EO, and  $CO_2$ . Therefore  $5 + 2 = 7$  calibration gases are required, for example, as shown in Table 3.

Calibration gas 1 is for determining the relative sensitivities, calibration gases 2–6 are for calibrating the fragmentation patterns, and calibration gas 7 is for calibration for the background peak heights.

It is normal practice to periodically check the validity of the calibration by analyzing a 'check gas', which is essentially representative of the sample gas. This check gas is often the same gas that is used to calibrate for the relative sensitivities. Analysis of this gas will also indicate when recalibration is required. Normally certain tolerances are applied as criteria for determining when recalibration is required. For components in the 1–100% range, these tolerances

**Figure 3** Flat-topped peaks obtained with magnetic sector instrument are advantageous for longer term reproducibility when analysis is performed by peak jumping because precise mass calibration is unnecessary. Also peak overlaps are simpler to deconvolute because the peak tops coincide over a more extensive mass.

**Table 2** Typical components and their fragmentation patterns used for analysis of ethylene oxide production

	Concentration (mol%)	Relative sensitivity	16	26	28	30	32	40	43	44
CH <sub>4</sub>	45.5	0.7	100							
N <sub>2</sub>	2	1			100					
C <sub>2</sub> H <sub>4</sub>	25	1		52.4	100					
C <sub>2</sub> H <sub>6</sub>	1	1.1		18.9	100	28.6				
O <sub>2</sub>	5	0.8	5.4				100			
Ar	10	1.4						100		
EO	1.5	0.5		4	6.6	2.3			25.2	100
CO <sub>2</sub>	10	1.2	5.8		5.7				0.02	100

are typically 1–2% relative. One normally expects results to remain within the tolerances over periods of a week or longer. However, in practice this very much depends on environmental factors such as ambient temperature and pressure, and on the exposure of the mass spectrometer ion source to various types of gases: effects are often referred to as ‘conditioning’. For example, online mass spectrometers used in the iron and steel industry for measuring mainly reducing gases such as H<sub>2</sub>, CO, and CH<sub>4</sub> are typically observed to remain within 1% (relative) tolerance with the check gases over months; however, if

**Table 3** Calibration gases required for analysis of ethylene oxide production

Calibration gas	1	2	3	4	5	6	7
% CH <sub>4</sub>	45.5						
% N <sub>2</sub>	2	95					
% C <sub>2</sub> H <sub>4</sub>	25		25				
% C <sub>2</sub> H <sub>6</sub>	1			5			
% O <sub>2</sub>	5	5					
% Ar	10						
% EO	1.5				1.5		
% CO <sub>2</sub>	10					100	
% He			75	95	98.5		100

such a system is exposed to oxygen containing samples, e.g., air, then larger deviations may be observed and recalibration may be required more frequently.

It is good practice to maintain a log of check gas analysis data. Ideally the data should be plotted and calculations performed to determine mean accuracies and values of standard deviations.

The most convenient way to assess the accuracy of analysis is to use the following expression:

$$\begin{aligned} \text{accuracy} = & (\text{mean accuracy of check gas}) \\ & + (\text{gas mixture manufacturer's} \\ & \quad \text{concentration tolerance}) \\ & + 3 \times (\text{standard deviation}) \end{aligned}$$

## Applications of Gas Analysis Mass Spectrometry

### Fermentation

Fermentation is defined as a chemical change brought about using microorganisms, e.g., in the biotechnology industry for production of pharmaceuticals, food additives, and animal feed-stuffs. Respiration is the process whereby an organism oxidizes food to produce energy. Control of fermentation processes to give enhanced yields requires the measurement of the respiratory gases oxygen and carbon dioxide. Mass spectrometry has become established as the preferred technique for accurate monitoring of oxygen consumption and carbon dioxide evolution. In recent years, with considerable growth in the biotechnology industry, this has become the most common application of online mass spectrometry. The analytical requirement for this application is for the measurement of oxygen and carbon dioxide to be better than  $\pm 0.01$  mol%, with a linearity over a decade of at least 0.2% relative and a calibration interval of at least 30 days.

Other components, which are sometimes monitored, include methanol, ethanol, water, ammonia, and sulfur compounds.

### Iron and Steel

In a blast furnace, coke is used to reduce the ore (iron oxide) to iron. Large quantities of gas, 'top gas', are formed at the top of the blast furnace as a result of the reduction of iron ore and the combustion of injected coal by injected blast air. Gas analysis is used to optimize the blast furnace process, including reducing the consumption rate of coke and controlling the temperatures inside the furnace. Analysis of hydrogen is very important for early detection of cooling water leaks which can be a considerable hazard.

In a steel plant, the basic processes for conversion of iron (from blast furnace) and scrap into steel are removal of sulfur and reduction in the carbon content to the required level. In the basic oxygen steel making process (BOS), basic oxygen furnace process (BOF), or Linz-Donawitz process (LD), typically the carbon content is reduced from 4–0.05%. In this process high purity oxygen is blown through molten hot metal via a lance at supersonic speed, in a process that lasts only  $\sim 30$  min. The oxygen reacts with carbon to produce CO and CO<sub>2</sub>; analysis of these gases is used to control operation of the lance to improve process efficiency and also to detect the process endpoint. The benefits are very great – process turnaround is improved, reblows are avoided, as is undesirable oxidation of the metal.

Ruhrstahl-Hausen (RH) and vacuum oxygen decarburization (VOD) are secondary steel-making processes to produce specialty steels. The process occurs under vacuum, which enables reduction of the carbon content to very low levels ( $< 0.01\%$ ) without undesirable oxidation of chromium. Special inlet systems have been designed to sample from these variable pressure processes and still maintain a constant flow of sample gas into the ion source.

Frequently in an integrated iron and steel works, there is a requirement to measure, very rapidly on-line, the calorific value and stoichiometric air requirement of fuel gas mixtures, in order to optimize burner performance and this is typically performed using mass spectrometry.

Other gases analyzed by online mass spectrometers in the iron and steel industry include those involved in coke ovens and direct reduction iron.

### Chemical

Examples of chemical processes using online gas analysis include those involving the production of the following materials: ethylene, ethylene oxide, polyolefins, ammonia, methanol, acrylonitrile, and vinyl chloride. Mass spectrometry is frequently used for control of steam reformers and coal gasification plants. Examples of species being monitored are nitrogen, oxygen, argon, carbon monoxide, carbon dioxide, and a variety of saturated and unsaturated organic compounds up to C<sub>6</sub>. Fast online mass spectrometric compositional gas analysis is being applied in many chemical applications to improve process control and, therefore, to give enhanced yield and improved product quality, but also frequently to ensure safety of operation.

Catalyst research where gases need to be analyzed often uses mass spectrometry because of its speed and flexibility.

**Figure 4** Peak observed with 1 ppt (parts per trillion) oxygen in nitrogen using an API source mass spectrometer.

### Semiconductor Manufacturing

Clean surfaces and pure reagent gases are essential requirements for semiconductor processing. Many fabrication techniques take place under vacuum, so partial pressure analysis is used to ensure that conditions are acceptable. For example, in a sputtering process, operating at a pressure of 0.01 mbar of argon, the presence of oxygen or water at a concentration as low as  $10^{-6}$  mole fraction may have an adverse effect on the process. It is therefore necessary to achieve a base pressure in the vacuum system better than  $10^{-7}$  mbar before back-filling with argon.

The gas composition can also be monitored during the fabrication process. The operating pressure is generally too high for direct operation of a mass spectrometer head, so the sample is taken to a separately pumped analyzer system. It is advantageous to employ an enclosed ion source, in which the ionization volume is operated at a pressure higher than that of the mass analyzer. This gives improved detection limits, since the effects of background pressure in the analyzer are reduced. Some designs can be operated with the ionization volume at or close to the process pressure, which makes for relatively non-invasive sampling and high sensitivity.

Detection limits of parts per million (mol) or even lower can be achieved for the common gases, such as hydrogen, low molecular weight hydrocarbons, nitrogen, oxygen, and water vapor.

Special techniques, such as API and collision-induced dissociation (CID) have been applied to detect

contaminants in extremely pure gases. For example, **Figure 4** shows the detection of parts per trillion (mol) of oxygen in nitrogen using a commercial instrument.

### Environmental Trace Gas Analysis

In trace gas analysis, it is required to monitor compounds, frequently organics, in atmosphere at low concentrations (parts per million (mol) or lower). Mass spectrometry offers versatile instrumentation for this, particularly when sensitivity and selectivity are enhanced by special inlet techniques or ionization processes.

A silicone-rubber membrane can be used to enhance the sensitivity to organics, detection limits of less than parts per million (mol) being obtainable for many species, and as low as parts per billion (mol) in some cases. When monitoring reactive species, an enclosed ion source is recommended for improved linearity. By using special ionization methods, the performance can be enhanced for specific compounds. For example, high-pressure ionization, followed by detection of negative ions, can yield a detection limit of parts per trillion (mol) for sulfur hexafluoride, which is strongly electronegative.

### Residual Gas Analysis in Vacuum Systems

Vacuum techniques are widely used in scientific research and in specialized industrial processes, such as manufacture of semiconductors. A pumping system is used to evacuate a housing to a pressure

sufficiently low for work to proceed. The process of evacuation may take several hours or even days if a very low pressure is required.

The pressure is limited by the rate at which material enters the gas phase in the housing, and by the capacity of the pumping system. If the gas load is too high, the system will fail to achieve its design pressure. In such a case, it is often helpful to establish the composition of the gas, since this will usually suggest appropriate remedial actions. A small mass-spectrometer, known as a 'residual gas analyzer' or a 'partial pressure analyzer' is well-suited to this task. Using helium as a tracer gas, the origin of leaks can be readily identified.

### Other Applications

Mass spectrometry has been extensively used to monitor the composition of the upper atmosphere. The requirements of compact size, light weight, and low power consumption stimulated the development of many different designs. Obtaining a representative sample presents unique problems, especially if radicals or ions are to be measured. The quadrupole is particularly suitable for monitoring energetic ions and neutrals.

The gases evolved during thermogravimetric analysis may be analyzed by mass spectrometry. A typical installation consists of a quadrupole mass spectrometer, fitted with an enclosed ion source, and sampling the effluent from a thermal analyzer via a heated capillary inlet with by-pass.

Isotope ratio monitoring, often needing very high precision and therefore requiring a magnetic sector

analyzer, is used for a variety of investigations in biological, medical, and geological research.

### Introduction

Since the late 1950s, mass spectrometry (MS) has been used to study peptides. However, until as recently as 15 years ago, mass spectrometers were used almost exclusively by organic chemists to investigate small molecules using field desorption techniques. The reason for this was that there were many problems with derivatization of the analytes and the low mass range was restrictive. But in the 1980s, two techniques became popular, which allowed direct

MS without derivatization – fission-fragment-induced desorption and fast atom bombardment, also known as liquid secondary ion mass spectrometry. Both were for proteins but still limited to some extent by sensitivity and mass range (up to 30 kDa). As most biomolecules are sensitive to organic solvents, substantial effort then went into bringing the biomolecules into the gas phase gently and in their natural state using 'softer' ionization techniques. So, in the past decade, protein identification and characterization became possible due to the soft ionization methods of matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) that allowed researchers to put molecules into the gas phase much more gently than previously. They also had good sensitivity and better mass ranges

sufficiently low for work to proceed. The process of evacuation may take several hours or even days if a very low pressure is required.

The pressure is limited by the rate at which material enters the gas phase in the housing, and by the capacity of the pumping system. If the gas load is too high, the system will fail to achieve its design pressure. In such a case, it is often helpful to establish the composition of the gas, since this will usually suggest appropriate remedial actions. ### Introduction

Since the late 1950s, mass spectrometry (MS) has been used to study peptides. However, until as recently as 15 years ago, mass spectrometers were used almost exclusively by organic chemists to investigate small molecules using field desorption techniques. The reason for this was that there were many problems with derivatization of the analytes and the low mass range was restrictive. But in the 1980s, two techniques became popular, which allowed direct

MS without derivatization – fission-fragment-induced desorption and fast atom bombardment, also known as liquid secondary ion mass spectrometry. Both were for proteins but still limited to some extent by sensitivity and mass range (up to 30 kDa). As most biomolecules are sensitive to organic solvents, substantial effort then went into bringing the biomolecules into the gas phase gently and in their natural state using 'softer' ionization techniques. So, in the past decade, protein identification and characterization became possible due to the soft ionization methods of matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) that allowed researchers to put molecules into the gas phase much more gently than previously. They also had good sensitivity and better mass ranges

(MALDI >300 kDa, ESI >100 kDa). These inventions triggered the widespread use of MS in proteomics (and earned the inventors John Fenn and Koichi Tanaka a shared Chemistry Nobel prize in 2002). There have also been developments in the detector end of the mass spectrometer with time-of-flight (TOF), ion trap, ion cyclotron resonance, and tandem mass spectrometers now available. Also, the exponentially growing amount of sequence information available in databases is helping enormously.

Proteomics is a far more complex field than genomics as it encompasses the characterization and functional analysis of all proteins that are expressed by the genome at a certain moment, under certain conditions. The proteome, unlike the genome, is also highly dynamic. Cellular processes, especially in disease states, are determined by multiple proteins, and thus it is important to be able to investigate not only on one single gene product (protein) but to be able to study the complete set of gene products (the proteome). Mass spectrometers are a valuable analytical tool used for measuring the molecular weight of a sample. This procedure is useful for the structural elucidation of organic compounds, for peptide or oligonucleotide sequencing, and for monitoring and detecting specific drug metabolites in biological matrices, to name but a few applications. Protein identification can also be carried out using certain types of mass spectrometers, usually tandem mass spectrometers, and fragmenting the sample and analyzing the products generated. Quantitative proteomics is now also possible using labeling techniques. MS is also extremely useful for the detection of post-translational modifications such as phosphorylation and glycosylation. Further investigation of protein structure such as folding and binding can also be achieved using mass spectrometric methods.

## **Protein and Peptide Molecular Weight**

Many analytical problems in protein and peptide research can be answered by obtaining the molecular mass of the compound. The mass accuracy is disputed somewhat but for a few picomoles of a >10 kDa molecule, somewhere ~0.1–0.01% would be expected depending on the ionization/desorption technique used and the mass analyzer employed. For large samples such as biomolecules, molecular weights can be measured to within an accuracy of 0.01% of the total molecular weight of the sample, i.e., within 4 Da or atomic mass units (amu) error for a sample of 40 000 Da. This is sufficient to allow minor mass changes to be detected, e.g., the substitution of one amino acid for another, or a post-translational modification. For small organic

molecules the molecular weight can be measured to within an accuracy of 5 ppm, which is often sufficient to confirm the molecular formula of a compound, and is also a standard requirement for publication in a chemical journal. Other important applications for molecular mass are confirmation of an expected structure, verification of an amino acid sequence (only in terms of the sums of the masses of the amino acids present), and monitoring of the formation or disappearance of reaction products.

## **Protein Identification**

In recent years, as a complement to Edman sequencing, mass spectral identification has emerged as a means to identify proteins. Proteomic analyses are usually carried out by using two-dimensional gel electrophoresis (2DGE) followed by MS and database searches. This approach is most suitable for the analysis of pure proteins or very simple mixtures. Since the mass of a protein alone is not enough information to confirm its identity, there are two main procedures used for identifying a protein by MS. The first is called peptide mass fingerprinting and is usually carried out using MALDI-TOF MS. The second, often employed when the first has not been totally successful, is called sequence tagging and is usually performed on an ESI-ion trap or ESI-quadrupole-TOF mass spectrometer. There is a third, more recent multi-dimensional or hyphenated technique called liquid chromatography–mass spectrometry (LC–MS) that can also be used under certain circumstances.

### **Technique 1 – Peptide Mass Fingerprinting**

Protein identification by in-gel digestion and peptide mass fingerprinting is almost a routine method in MS laboratories. The protein sample is digested with a specific enzyme, e.g., trypsin, which cuts in a sequence-specific manner to produce a defined set of peptides. Trypsin is useful for mass spectrometric studies because each proteolytic fragment contains a basic arginine or lysine amino acid residue, and thus is eminently suitable for positive ionization mass spectrometric analysis. The peptides are extracted from the gel, sometimes desalted and then the digest mixture can be directly deposited onto the MALDI target plate and the rest of the sample can be stored for subsequent analysis, e.g., by ESI-MS. The peptide mixture is then analyzed by MS to produce a rather complex spectrum from which the molecular weights of all of the proteolytic fragments can be read. This spectrum, with its molecular weight information, is called a peptide map or peptide mass fingerprint (PMF). This PMF can be used to search protein

databases. If the protein already exists on a database, then the peptide map is often sufficient to confirm the protein (Figure 1).

A search algorithm is used that carries out virtual digests of protein sequences based on the sequence-specificity of trypsin and then calculates the masses of the predicted peptides from first principles (for example, by adding up the masses of the individual atoms). The hits are generally ranked according to the number of peptides that match. Unique identification does not require the whole protein to be covered by the tryptic peptides. Usually 10–20% coverage is sufficient. The great precision of mass spectrometers nowadays allows the discrimination of even extremely similar proteins, differing in structure by only one amino acid. The mass accuracy is an important aspect of this approach and with a mass accuracy of 10–30 ppm for peptides in a MALDI-TOF system, usually four or five peptides are enough to identify the protein unambiguously. MALDI produces singly charged ions and hence the spectra are easy to interpret.

There are now available automated systems capable of cutting the spots out of the gel, digesting the samples, desalting, and then spotting onto the

MALDI plates. Data processing and database searching can also be automated but in practice, when small amounts of protein digests are analyzed, the spectra have to be checked manually before database searching. Instead of excising individual spots from the gel, some researchers proteolytically digest all proteins on the gel at the same time, transfer to a membrane, and directly scan by MALDI-TOF. This molecular scanning approach takes an enormous amount of time and memory, e.g., for a  $16 \times 16 \text{ cm}^2$  membrane, 36 days of continuous scanning and more than 40 Gb of raw data.

PMF is only successful when the digested protein exists in the protein or genomic databases, if the fingerprint is unique, and when four or more peptides are obtained by MALDI. If PMF is not successful, it will be necessary to obtain sequence information from the peptides. The most common way to do this is by ESI-MS/MS that is described below.

## Technique 2 – Sequence Tagging

This second approach takes the peptides after digestion and fragments them in the tandem mass spectrometer yielding partial random amino acid

**Figure 1** The mass accuracy of the peptides measured is critical in PMF; therefore, the spectra have to be internally calibrated. If trypsin is used for in-gel digestion, the enzyme will also cleave itself into fragments, which can be used for calibration. (Reprinted with permission from Nyman TA (2001) The role of mass spectrometry in proteome studies. *Biomolecular Engineering* 18(5): 221–227; © Elsevier.)

sequences from the peptides (sequence tags). Database searches are performed using both the molecular weight information and the sequence tags, and the chance of a unique hit in the database is considerably enhanced. The advantage of using the sequence tag approach is that database searches are much more accurate when both peptide molecular weight and sequence information are used compared with molecular weight only. A sequence tag from one peptide is often sufficient to identify the protein. The fragment ions can also be ordered by size and the masses of sequential fragments used to establish which amino acids have been cleaved off. In this way, the protein sequence can be established and used to search sequence databases to find related rather than exact matches. If a match is not found, additional peptides have to be mass spectrometrically sequenced. Determination of the total sequence of a protein takes considerably more effort. Compared to MALDI-MS, ESI-MS is more time consuming and laborious. The analysis time is also limited since the liquid sample is being consumed throughout the ESI-MS experiment. ESI-MS can be automated by using LC prior to the MS. LC separation before MS is especially useful when complex mixtures are being analyzed. One useful strategy is to get the software to switch from MS mode to MS/MS mode when a peak elutes from the LC into the MS causing a surge in the ion current. This is a product ion scan. This generates very useful data in an automated way and can be set up to automatically fragment and collect MS/MS data on any number of peptides observed in the MS spectrum based on their intensity,  $m/z$  value, or charge state.

### Technique 3 – LC-MS Approach

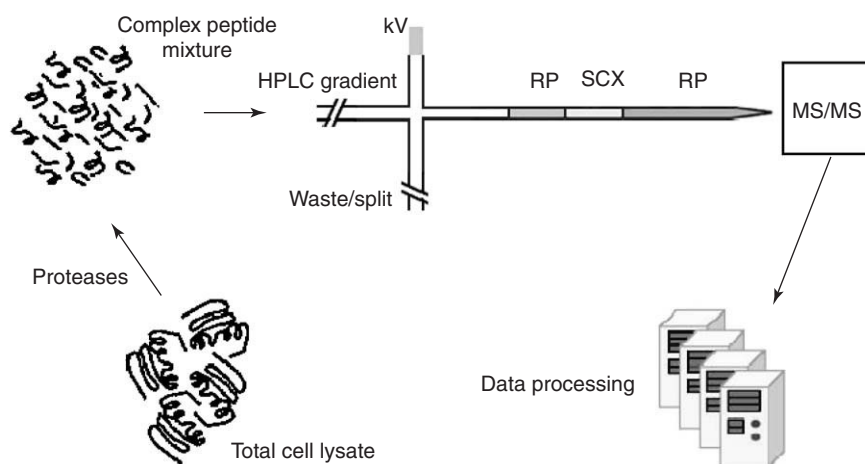

In this approach, the whole cell lysate is digested chemically or with a protease. This generates a very complex set of peptides. For the analysis of such complex mixtures, several multidimensional techniques are possible involving combinations of chromatography and/or capillary electrophoresis (CE). Multidimensional chromatography coupled to MS/MS for proteomics has been called multidimensional protein identification technology (MudPIT). One group of researchers has used MudPIT to analyze the proteome of *Saccharomyces cerevisiae* in which a total of 1484 proteins were detected and identified. Even low abundance proteins such as transcription factors and protein kinases were identified. Multidimensional LC-MS has also proved very important for the analysis of membrane proteins that are usually underrepresented on conventional 2D gels.

MudPIT uses the ability of tandem mass spectrometers to select and analyze peptides from protein

mixtures that have been proteolytically digested. The peptides then serve as surrogate markers for the protein sequence. Proteins are identified by searching the resulting tandem mass spectra through sequence databases. Because digested protein mixtures create complex mixtures of peptides, high-performance separation techniques are required to resolve the peptides prior to entering the tandem MS. The online MudPIT process fully automates the separation and identification of proteins from complex mixtures. The first step in such an experiment is the enzymatic digestion of a protein mixture to produce a more complex peptide mixture. A specially packed bi- or triphasic column containing sections of strong cation exchange (SCX) and reversed-phase (RP) materials is used to separate the peptides. Peptides are eluted from the SCX phase onto the RP part of the column in a series of salt steps that increase in concentration. A gradient in the latter RP part of the column separates and delivers the peptides onto the MS in manageable numbers. MudPIT appears to introduce very little bias in its sampling of proteins from the cell but the sample preparation procedure is very important. MudPIT-type analyses require high throughput database searching techniques (Figure 2).

### Quantitative Proteomics

An increasing emphasis in proteomics is the quantitation of protein content rather than simple determination of presence or absence. The traditional way to do this is by comparing the densities of corresponding spots in different 2D gels. This provides only a rough estimate, as it is very dependent on sample processing, staining efficiency of individual gels, and subsequent spot detection. As MS is not inherently quantitative, other methods have appeared that allow it to be. These methods are based on the direct/linear relationship between the amount of peptide/protein in a particular sample and its peak height in the mass spectrum. However, direct quantitation of proteins and peptides is very difficult because the absolute intensities of the detected ions are determined by their physiochemical properties. Therefore, internal standards are needed with chemical properties very similar to the analyte. Absolute quantities of peptides can also be measured using known quantities of peptide standards, but the method is not suitable for proteins. Protein quantitation can be achieved by labeling with a mass label to differentiate the same proteins for relative quantitation. This technique is called isotope dilution and involves spiking the sample with the analyte modified with a stable isotope, e.g., H-2, C-13, or N-15. The intensity ratio of the internal standard to the analyzed

**Figure 2** Schematic overview of the three-phase multidimensional protein identification technology (MudPIT). A total cell lysate is digested by a protease (i.e., trypsin). The complex peptide mixture is loaded on a capillary column. The LC gradient is delivered to a junction and part of the flow is split off through the column to reduce the flow to a couple of hundreds of nanoliters per minute. The peptides are separated by a tri-phasic column, with in line a reversed phase, strong cation exchange, and another reversed phase, before they enter the ionization source of the mass spectrometer. Each peptide elutes in a time window of several seconds allowing the mass measurements and the determination of peptide sequences by tandem mass spectrometry. These data are used for protein identification using database searches. (Reprinted with permission from Romijn EP, Krijgsveld J, and Heck AJR (2003) Recent liquid-chromatographic-(tandem) mass spectrometric applications in proteomics (review). *Journal of Chromatography A* 1000(2): 589–608; © Elsevier.)

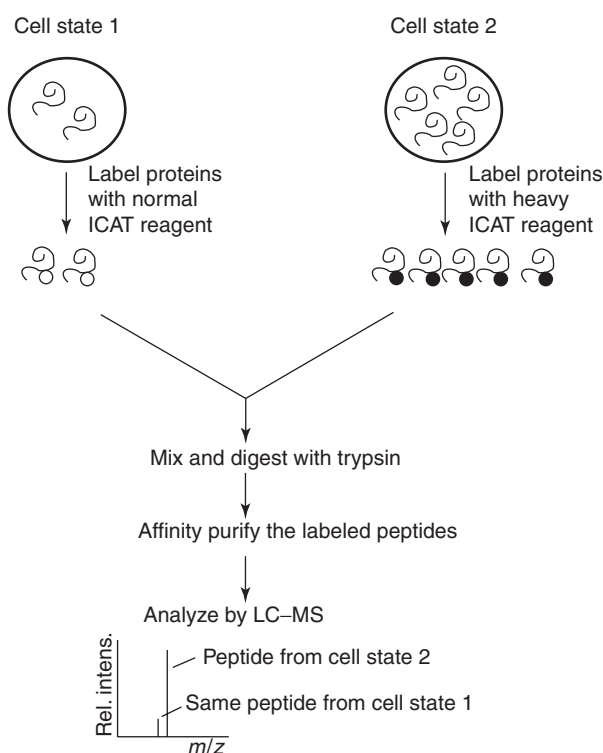

compound is then used for quantitation. If the absolute concentration of the standard is known, then the quantity of the analyte can be determined accurately. There are four main types of labeling strategies. The first method uses metabolic labeling to incorporate N-15 into peptides. The second method uses proteolytic digestion to generate peptides in the presence of O-18-containing water to incorporate a label. The third method uses covalent labeling that is usually targeted at reactive amino acid residues and generally the label contains deuterium atoms in place of hydrogen atoms. The last method is protein derivatization with isotope-coded affinity tags (ICAT) (Figure 3).

In ICAT labeling, tags of different isotope composition (heavy and light) are reacted with two protein populations to quantitatively differentiate between proteins altered in abundance. The ICAT reagent itself consists of a thiol-specific group, a linker region containing either eight hydrogen atoms (d, light) or eight deuterium atoms (d8, heavy), and a biotin group. A protein sample from one source is reacted with the d form of the tag and another with the d8 version. These samples are then combined and digested with a proteolytic enzyme. The biotin moiety is then used to selectively capture reacted peptides using avidin chromatography. Since the method targets cysteine-containing peptides, this results in a substantial reduction in sample complexity so that a reduced number of peptides need to be analyzed. Combined LC-MS/MS can be used at this stage for

identification by peptide fragmentation and the abundance ratio of peptides derivatized by either label can be determined by integration of the peaks separated by 8 Da. One example of a large-scale study applying ICAT showed the differential analysis of microsomal fractions of human cells that resulted in the identification and quantitation of 491 proteins.

### Analysis of Co- or Post-Translational (Chemical) Modifications

Further complicating the analysis of proteins are the chemical modifications that can occur co-translationally or post-translationally to modify or regulate their functions. There are more than 100 modification types already described in the literature and it is most likely that more will be found. MS has been used to study many of them such as phosphorylation, glycosylation, methylation, formylation, acetylation, palmitoylation, lipidation, and sulfonation. MS is particularly important for this application as recent studies have shown that mRNA expression and protein levels do not always correlate. Proteins can be post-translationally modified or present as different isoforms, and these modifications cannot be predicted from the corresponding DNA sequences. Post-translational modifications play an important role in determining protein function, but identifying peptides containing these modifications poses many challenges. Modified peptides such as those bearing

**Figure 3** The principle of ICAT. The ICAT reagents have a thiol-specific reactive group and a biotin group. This way it is possible to label all peptides containing cysteines and then avidin affinity purify them. The cysteines in proteins in cell state 1 are labeled with normal ICAT reagent, and the cysteines in cell state 2 with deuterated, heavy ICAT reagent. Then the samples are pooled, digested with trypsin, and ICAT-labeled peptides are isolated with affinity chromatography followed by analysis with LC-MS. Protein levels can be quantitated by measuring peak ratios between normal ICAT-derivatized peptide and deuterated ICAT-derivatized peptide. For protein identification peptides are sequenced by MS/MS. (Reprinted with permission from Nyman TA (2001) The role of mass spectrometry in proteome studies. *Bio-molecular Engineering* 18(5): 221–227; © Elsevier.)

the important phosphorylation modification may produce fragment ion spectra more complex than normal peptides, complicating their interpretation. This means that augmented forms of existing databases matching algorithms typically take far longer to run on spectra when modification possibilities are taken into account. The use of MS to investigate phosphorylation, glycosylation, and ubiquitination modifications are discussed below.

### Phosphorylation

Although phosphorylation is observed on a number of amino acid residues, by far the most common and most important sites are on serine, threonine, and tyrosine residues. Reversible phosphorylation and dephosphorylation is an extremely important modulator of protein function. MS has emerged as

an increasingly viable tool for the task of elucidating the presence and sites of O-phosphorylation. MS can firstly and accurately provide the molecular mass of the intact phosphorylated protein. When the molecular mass is compared with that of the unmodified protein and/or the protein treated with phosphatase, the number of attached phosphate groups can be determined. To fully understand protein phosphorylation, it is necessary to identify the exact amino acid residues that become phosphorylated.

Protein phosphorylation can be studied by MS provided there is a good amount of starting material (more than a spot on a gel) and that the resolution of the mass spectrometer is good. The first step in analysis of phosphoproteins by MS is enrichment. This is because MS of proteolytic digests of proteins rarely provides 100% coverage of the protein sequence. Phosphorylation is often sub-stoichiometric such that the phosphopeptide is present in lower abundance than other peptides from the initial protein. Also, the MS response to a phosphopeptide may be suppressed relative to its unphosphorylated counterpart, so analysis of phosphopeptides is easier if they are first enriched and the best way to achieve this is to use immobilized metal affinity chromatography. In this technique, metal ions are bound to a chelating support. Phosphopeptides are selectively bound because of the affinity of the phosphate groups for metal ions. The phosphopeptides can then be released by high pH or phosphate buffer. Other methods of enrichment for phosphopeptides include the use of antibodies for immunoprecipitation and chemical tagging of phosphorylation sites. The second step in the analysis of phosphoproteins is to perform trypsin digestion and generate a PMF by MALDI-MS. Examination of the peptide map for peptides shifted by multiples of 80 Da ( $\text{HPO}_3$ ) or 98 Da ( $\text{H}_3\text{PO}_4$ ) can be effective in providing a signature for phosphopeptides. Differences in the peptide map before and after phosphatase treatment can further aid analysis since their molecular weight will be reduced by 80 or 98 Da after the phosphatase treatment. The peptides that lose their phosphate group can be sequenced from the MALDI sample. Subsequent MS analysis can then be offline or online, perhaps with a hyphenated technique in between such as LC or CE. In order to quantify phosphorylation, some workers have used the relative intensities of the peptide signals by ESI-MS as a measure of the extent of phosphorylation. Isotope labeling or the introduction of a mass tag are alternative methods of quantitation.

Other mass spectrometric experiments that can be useful for studying phosphorylation include post-source decay, precursor ion scan, neutral loss scanning, and stepped skimmer potential. In order to

**Figure 4** Phosphopeptide identification by MALDI-TOF-MS mapping combined with alkaline phosphatase treatment. (A) The MALDI-TOF-MS spectrum of a proteolytic digest. Phosphopeptides are indicated by peaks shifted by multiples of 80 Da ( $\text{HPO}_3 = 80 \text{ Da}$ ) relative to predicted unphosphorylated peptide masses. (B) The disappearance of such peaks upon treatment with a phosphatase confirms their identity as phosphopeptides. identify the positions of phosphorylation sites, collision induced dissociation (CID) MS/MS by ESI is commonly used. Fragment ions can be measured and loss of phosphate as  $\text{HPO}_3$  or  $\text{H}_3\text{PO}_4$  is a favored fragmentation event. Separation methods can be coupled to the MS online in order to improve the CID analysis of complex proteolytic mixtures (Figure 4).

### Glycosylation

Protein glycosylation is another post-translational modification that is essential for *in vivo* functions. Glycoproteins play an important role in cell–cell and cell–substratum recognition events in multicellular organisms. Glycosylation is probably the most complex post-translational modification. There are a number of types of glycosylation but one in particular – O-Glc-NAc modification – is of great biological relevance and can be studied by MS. This type of modification is believed to be a regulatory modification. Most known O-Glc-NAc proteins are also phosphoproteins. Historically, the method used to study these modifications involved galactosyltransferase radiolabeling of O-Glc-NAc moieties, generation of glycopeptides by proteolytic cleavage, purification by LC, and Edman protein sequencing. A more elegant approach involves enrichment of O-Glc-NAc-modified peptides from complex mixtures

using *Ricinus Communis* (RCA 1) affinity chromatography followed by galactosyltransferase labeling. The labeling of an O-Glc-NAc group with galactose using galactosyltransferase produces a disaccharide substituent with a diagnostic mass of  $m/z$  366. After enrichment, the peptides are separated by LC and analyzed by MS. This is achieved by specifically searching for peptides carrying the O-Glc-NAc modification by the monitoring of a specific reporter ion and the identification of the original protein from which the peptide came by CID and database searching. The removal of this disaccharide from the glycopeptide requires much less energy than the fragmentation of the peptide backbone. It is possible to take advantage of this difference in fragmentation energy. Both operations are performed automatically and simultaneously with femtomole sensitivity. In glycosylation studies, the glycans are liberated from the protein and the glycan structures are determined from the free glycans. The glycan structures can be characterized by combining MALDI measurements with exoglycosidase digestions. If more detailed structural information is required, ESI-MS can be used with product ion scans.

### Ubiquitination

Protein ubiquitination is among the most common of all post-translational modifications. Ubiquitin plays an important role as a signal molecule for protein degradation in eukaryotes and as a regulator of protein activity and localization. One strategy that has been used to analyze protein ubiquitination is by coupling LC and MS. Ubiquitin conjugates were purified from a yeast strain expressing Histidine-tagged ubiquitin or a control strain by denaturing nickel affinity chromatography. Following trypsin digestion, a ubiquitin-conjugated protein contains a di-glycine residue of ubiquitin covalently attached to a lysine residue that is resistant to proteolysis. The resulting peptides are separated by SCX chromatography. All fractions are sequentially analyzed by nano-LC–MS/MS. Not only can the proteins be identified in this way, but the exact sites of ubiquitination can also be identified in a percentage of the cases.

### Further Study of Protein Structure

Primary protein structure is the sequence of the amino acids in that protein and this has been discussed in the section on Protein identification. Secondary protein structure is the arrangement of the amino acid sequence that makes up the polypeptide backbone of the protein. Tertiary protein structure is the overall

three-dimensional folded shape of the protein when it is in its native state. Quaternary structure means the arrangement of subunits within multi-subunit proteins, e.g., hemoglobin. Therefore, together, secondary, tertiary, and quaternary structures govern how proteins fold and interact with each other and other molecules. Methods employing ESI-MS have been able to provide information on a protein's higher-order structure such as the use of hydrogen/deuterium exchange experiments to study the folding rates of hen egg-white lysozyme. Hydrogen/deuterium exchange experiments have also allowed determination of the relative amounts of  $\alpha$ -helices and  $\beta$ -sheets in peptides.

Protein-protein interactions such as those between antibody and antigen and enzyme and substrate pairs can be studied by MS. Since many cellular functions are performed by protein complexes and not by individual proteins, it is important to be able to identify the interacting protein components. As ESI is a gentle technique, the detection of weakly bound (noncovalent) complexes in the gas phase is possible. There is evidence to suggest that these ESI-MS observations can reflect the expected interactions in solution phase and can even determine the strength of these interactions. Mass spectrometric experiments with multimeric proteins can yield information on both the stoichiometry and molecular nature of subunit interactions.

Peptide-metal and protein-metal interactions can also be studied using MS and the specific binding of metals can be distinguished from nonspecific interactions such as adduct formation.

## Future Prospects

At the moment, proteome analyses are normally carried out by 2DGE followed by MS, and MS has proven to be the method of choice for large-scale, high-throughput protein identification. The main drawback of this procedure is the 2DGE step where low abundance proteins often cannot be detected and it is also quite a laborious and sometimes irreproducible technique. LC linked to MS has gone some way toward overcoming the shortcomings of the 2DGE step. The technology for proteome analysis is becoming more and more a three-step procedure – separation science chromatography for separation of the proteins and peptides, MS for the identification and characterization of these biomolecules, and bioinformatics for data management. It is expected that nano-LC combined with tandem MS and database searching will dominate the field of protein identification going forward.

Another approach that is being tried is called *de novo* peptide sequencing by MS and it differs substantially from the peptide identification processes that rely on the presence of the target peptide sequence in a supplied database. The *de novo* challenge is to infer a peptide sequence directly from the spectrum without any other information as to what the sequence may be. Several attempts have been made but success has been limited by data quality and hindered by the complexity of accurately predicting fragment ion spectra. It is unlikely ever to be as sensitive as current bioinformatics and database searching methods but with constantly emerging improvements being made in the field of MS for peptides and proteins, there may come a time in the future when this becomes the method of choice.

### Introduction

Generally, techniques to detect genetic diversity are based on the known genomic sequence. Specific genes are often amplified by the polymerase chain reaction (PCR). The detection of genetic variants involves properties of DNA that indirectly reflect sequence: e.g., recognition of a region in a strand by a complementary sequence (as observed with microarrays), distinct mobility on electrophoretic separation, or differential digestion of specific DNA regions by enzymes (e.g., restriction enzymes). Alternatively, mass spectrometry (MS) directly determines DNA structure. Electrospray ionization (ESI)-MS discriminates two structurally related PCR products by molecular weight (MW) difference. Whilst tandem mass spectrometry (MS/MS) differentiates PCR products by changes in molecular fragmentation pattern (analogous to an enzymatic restriction digest but providing much greater information) directly reflecting sequence differences at each position on both DNA strands. Examples are given here to illustrate the type of information that can be obtained using ESI-MS and MS/MS analysis involving: (1) discrimination of structurally related PCR products from genetically related bacterial species or strains with implications for detection of a biological warfare attack or forensics; or (2) recognizing molecular diversity among normal or diseased human populations (e.g., cancer patients) with a role in understanding etiology, diagnosis, and treatment.

The state-of-the-art technology to be discussed here employs two techniques that are each powerful in their own right: PCR and tandem mass spectrometry. However, when used together they display synergism that allows information to be obtained, in real time, that is difficult to obtain by either alone. Classical PCR involves detection of a PCR by electrophoretic mobility on a gel, which is time

consuming. Real-time PCR is distinct from classical PCR, in that electrophoresis is avoided and the PCR product is detected simply by an increase in fluorescence. For example, the PCR reaction mixture contains a dye that is not fluorescent, except when bound to double stranded (ds) DNA. Thus, as the amount of ds DNA increases on amplification, fluorescence also increases. Unfortunately, PCR is a technique generally used by molecular biologists, whereas MS is employed traditionally by analytical chemists. Thus, methodologies, concepts, and terms used by one discipline may be unfamiliar to the other. This explains why, in certain places, definitions are given here that might be obvious to one group but not the other. It also helps explain why, to this point, PCR-MS and PCR-MS/MS has largely been used by a handful of researchers rather than as a routine diagnostic tool. It is argued here that PCR-MS and MS/MS technology has matured to a stage that widespread application is indeed not only possible but desirable. However, mutual education and/or collaboration of molecular biologists and analytical chemists is essential, and this is part of what we attempt to accomplish here in this article.

For the non-mass spectrometrists, it should be pointed out that nowadays the analysis of large molecules (e.g., PCR products) is primarily based on matrix-assisted laser desorption ionization (MALDI) mass spectrometry or ESI ionization. In the former case, the sample is present within an energy-absorbing matrix on a surface. When hit with a laser beam, the matrix absorbs the energy, transferring it to the molecule of interest (e.g., DNA). Generally, only a singly ionized species is produced having a single charge. In contrast, ESI-MS is performed in solution and the sample is introduced into the source of the mass spectrometer using a syringe pump. The solution is sprayed, in the presence of an electrical field, and charges are transferred to the resulting droplets. As the droplets evaporate, the charge is transferred to molecules present within the droplet. Ions are produced that can have multiple charge states (e.g., for a 30-mer, anywhere from  $-1$  to  $-30$  charges). Since mass analyzers (the next stage after the source)

### Introduction

Generally, techniques to detect genetic diversity are based on the known genomic sequence. Specific genes are often amplified by the polymerase chain reaction (PCR). The detection of genetic variants involves properties of DNA that indirectly reflect sequence: e.g., recognition of a region in a strand by a complementary sequence (as observed with microarrays), distinct mobility on electrophoretic separation, or differential digestion of specific DNA regions by enzymes (e.g., restriction enzymes). Alternatively, mass spectrometry (MS) directly determines DNA structure. Electrospray ionization (ESI)-MS discriminates two structurally related PCR products by molecular weight (MW) difference. Whilst tandem mass spectrometry (MS/MS) differentiates PCR products by changes in molecular fragmentation pattern (analogous to an enzymatic restriction digest but providing much greater information) directly reflecting sequence differences at each position on both DNA strands. Examples are given here to illustrate the type of information that can be obtained using ESI-MS and MS/MS analysis involving: (1) discrimination of structurally related PCR products from genetically related bacterial species or strains with implications for detection of a biological warfare attack or forensics; or (2) recognizing molecular diversity among normal or diseased human populations (e.g., cancer patients) with a role in understanding etiology, diagnosis, and treatment.

The state-of-the-art technology to be discussed here employs two techniques that are each powerful in their own right: PCR and tandem mass spectrometry. However, when used together they display synergism that allows information to be obtained, in real time, that is difficult to obtain by either alone. Classical PCR involves detection of a PCR by electrophoretic mobility on a gel, which is time

consuming. Real-time PCR is distinct from classical PCR, in that electrophoresis is avoided and the PCR product is detected simply by an increase in fluorescence. For example, the PCR reaction mixture contains a dye that is not fluorescent, except when bound to double stranded (ds) DNA. Thus, as the amount of ds DNA increases on amplification, fluorescence also increases. Unfortunately, PCR is a technique generally used by molecular biologists, whereas MS is employed traditionally by analytical chemists. Thus, methodologies, concepts, and terms used by one discipline may be unfamiliar to the other. This explains why, in certain places, definitions are given here that might be obvious to one group but not the other. It also helps explain why, to this point, PCR-MS and PCR-MS/MS has largely been used by a handful of researchers rather than as a routine diagnostic tool. It is argued here that PCR-MS and MS/MS technology has matured to a stage that widespread application is indeed not only possible but desirable. However, mutual education and/or collaboration of molecular biologists and analytical chemists is essential, and this is part of what we attempt to accomplish here in this article.

For the non-mass spectrometrists, it should be pointed out that nowadays the analysis of large molecules (e.g., PCR products) is primarily based on matrix-assisted laser desorption ionization (MALDI) mass spectrometry or ESI ionization. In the former case, the sample is present within an energy-absorbing matrix on a surface. When hit with a laser beam, the matrix absorbs the energy, transferring it to the molecule of interest (e.g., DNA). Generally, only a singly ionized species is produced having a single charge. In contrast, ESI-MS is performed in solution and the sample is introduced into the source of the mass spectrometer using a syringe pump. The solution is sprayed, in the presence of an electrical field, and charges are transferred to the resulting droplets. As the droplets evaporate, the charge is transferred to molecules present within the droplet. Ions are produced that can have multiple charge states (e.g., for a 30-mer, anywhere from  $-1$  to  $-30$  charges). Since mass analyzers (the next stage after the source)

generally separate by the mass-to-charge ratio, simple spectra are generated for MALDI-MS but ESI spectra are considered to be complex. However, as noted below, a simple computer-assisted operation (deconvolution) converts the complex plots (mass spectra) of mass/charge ratios versus abundance to molecular weight also versus abundance. When plotted in this fashion, ESI mass spectra resemble MALDI spectra and are readily interpreted. The longer the DNA sequence that can be analyzed the more information that can be obtained, and generally MALDI-MS has been most successfully used for analysis of low mass DNA (e.g., primer extension reactions). Furthermore, it is only in the past couple of years that MALDI-MS/MS has begun to become more widely available, thus analysis of PCR products has been very limited to this point. Thus, this article will focus primarily on ESI-MS and MS/MS analysis of PCR products.

PCR is the most widely used technique, as the first step, in technology to analyze structure diversity in DNA. Minor variations in sequence (e.g., single nucleotide polymorphisms or the presence of tandem repeats (variable numbers of a short sequence present sequentially in a single stretch of DNA)) are detected or the presence of more than one copy of a gene (e.g., heterozygotes (two copies differing in sequence, one from the mother and one from the father) versus homozygotes (both copies are the same)). PCR employs specific sets of primers to amplify only a gene of interest. Femtogram to picogram amounts of DNA are used to generate high nanogram or even microgram amounts of the gene of interest. Classically, in trace analysis, the analytical chemist uses liquid chromatography, or other separation techniques, to concentrate on analyte present in low concentration and to separate it from high abundance background peaks that would otherwise confound the analysis. However, using PCR such separations are often unnecessary even when performing trace analysis on complex clinical or environmental samples (e.g., detecting bacterial infection). As noted above, generally, PCR products are characterized by classical molecular biology techniques (e.g., arrays or electrophoresis). Alternatively, one of the most powerful techniques to obtain structural information is MS. This is evidenced by the proteomics revolution where the engine driving this has been MS. MS could have a similar impact in the molecular diagnostics arena.

Over the past decade, ESI-MS analysis of PCR products has become a mature technology for genetic discrimination. The more mainstream technique, real-time PCR, is also a powerful approach that provides a simple yes or no answer, by generation of a fluorescent signal, as to the presence of a

characteristic sequence. However, there may be too many false positives in certain situations (e.g., detection of a terrorist attack) to be acceptable. It is also difficult to use real-time PCR to detect minor sequence variations. The only difference between the stages in sample preparation, for real-time PCR or PCR-MS relate to an additional clean-up step for PCR-MS and PCR-MS/MS. However, a great deal of structural information is additionally obtained by mass spectrometric analysis. The primary steps are first sample collection. This can involve an air sampling pump and either an impinger (liquid collection) or an impactor (for collection onto a filter) for environmental samples. Clinical samples (e.g., body fluids) are, of course, more simply collected. The next step involves release of DNA from cells using organic solvents to lyse cells. For bacteria, the cell membrane is encased in a tough cell wall that must be broken (e.g., shaking with glass beads). The DNA is purified to remove potential contaminants that otherwise will inhibit the PCR reaction. Next, real-time PCR is performed to generate the gene of interest. In real-time PCR, the fluorescent signal is generated as the DNA is amplified, i.e., amplification and detection occur together in a standard PCR instrument. However, additionally for MS analysis of PCR products, purification of the PCR product must be performed prior to MS or MS/MS analysis. As noted below this is primarily to eliminate low mass constituents of the PCR reaction mixture that otherwise inhibit ionization in the mass spectrometer.

Currently, PCR and MS are performed using two separate instruments. However, there is no reason that PCR followed by simple automated clean up and MS could not be incorporated into a single integrated instrument. Essentially, every configuration of modern ESI mass spectrometer has been used successfully for analysis of PCR products, including from the highest to the lowest resolution, i.e., Fourier transform ion cyclotron resonance, magnetic sector, triple quadrupole, quadrupole-time of flight (Q-TOF), and ion trap. MS discriminates two structurally related PCR products by MW difference. Mass accuracy is needed to differentiate the pairs of coding or noncoding strands (each pair may differ by 9–40 Da, adenine to thymine (A to T) and guanine to cytosine (G to C) switch, respectively). Large PCR products in the range 223–500 nucleotides have been analyzed with the required precision. MS/MS allows for the differentiation of PCR products of closely related sequence, by fingerprint, even if they have the same nucleotide composition; fragmentation of the parent molecule occurs in the tandem mass spectrometer (analogous to a restriction digest pattern). A particular mass is selected that is collided with a collision

gas (usually argon or helium). The DNA strand breaks into fragments, at each nucleotide position, by scission of phospho-diester bridges. Thus, a series of fragments are generated, rather like a Sanger sequencing ladder, each differing from one another by a single nucleotide. Unfortunately, each piece can differ by charge and mass and there is further complication that there are four possible breakage points within a phospho-diester bridge. Thus, MS/MS spectra are much more complicated than MS spectra and currently it is difficult to visually read sequence, although this is possible with computer-assisted software. Alternatively, MS/MS spectra can be compared to detect sequence variation without the need for sequencing.

## MS Analysis of PCR Products

Samples must be cleaned up prior to MS analysis. Other components of the PCR reaction (e.g., metal ions and nucleotides) inhibit ionization in the mass spectrometer source or preferentially ionize. Furthermore, metal ions can bind to the phosphate backbone of DNA, thus changing the mass and complicating mass spectral interpretation. When PCR-MS was first introduced, in the mid-1990s, there was a great deal of interest in developing a simple approach for clean-up of PCR products for MS analysis. As regards ESI-MS analysis, a single approach, involving ethanol precipitation, was used reliably among a variety of laboratories and rapidly became the gold standard. Generally, clean-up is performed with ethanol precipitation in the presence of ammonium hydroxide. Ammonia replaces the metal ions and dissociates from the DNA in the mass spectrometer. Unfortunately, this is time consuming, taking a few hours or more commonly overnight for the precipitation. Although after precipitation the pellet is rapidly washed with ethanol and ethanol-water. Thus, when rapid analysis is required (e.g., for biodection) this approach is inadequate. Recently, a new approach was introduced that shows great promise. The PCR product is bound to a weak anionic exchange column (e.g., a Zip-Tip, Millipore, Bedford, MA) and washed to remove low mass materials (e.g., nucleotides and dideoxynucleotides) that do not bind to the column. The column is then washed with solutions containing high concentrations of ammonia to remove metal ions. After elution with methanol-water, the sample is ready for MS analysis. Comparable results are obtained by the two approaches (see Figure 1).

Two variations for analysis of PCR products by ESI-MS have emerged: (1) direct-injection MS and tandem mass spectrometry and (2) liquid

**Figure 1** MW of 46bp PCR product of mutant human *K-ras* codon 12 variant TGT determined using ESI-quadrupole MS after clean-up of PCR product by (A) ethanol precipitation or (B) Zip-Tip. The spectra have been deconvoluted to simplify visual discrimination. Predicted masses for the coding and noncoding strands are 14 261.3 and 14 039.1 Da, respectively.

chromatography-mass spectrometry (LC-MS) and tandem mass spectrometry (LC-MS/MS). In the former approach, sample clean-up is performed manually and, as noted above, must be simple and preferably rapid. While in the latter approach, clean-up is carried out automatically by the LC. The advantages of LC-MS and LC-MS/MS are that more complex samples can be analyzed, since there is the opportunity to separate a sample into components by LC, before entry into the mass spectrometer. Additionally, it is possible to run large batches of samples in an entirely automated fashion. However, LC analysis is much more complicated instrumentally than direct injection. The molecular biology community is not

**Figure 2** Measured MW of PCR products, 16S–23S interspace region determined using ESI-quadrupole MS. (A) *B. anthracis* (89 bp, predicted mass of coding and noncoding strands; 27 237.8 and 27 618.9, respectively) and (B) *B. subtilis* (114 bp, predicted mass of coding and noncoding strands; 34 972.8 and 35 329.0, respectively).

generally well-versed in LC instrumentation, preferring to use electrophoresis. Thus, they are more likely to employ direct MS analysis of PCR products. It is worthy of note that modern MS instruments (e.g., MALDI-TOF or ESI-ion traps) are run by Windows-based computer software. There is very little to learning how to introduce a DNA sample into either instrumental configuration. Indeed, when MS spectra are plotted as mass versus abundance, there is little data interpretation required. MS/MS spectra are quite complex, and further simplification of computer-assisted data handling is still needed. Although developments in MALDI-MS/MS may help, simpler spectra than for ESI MS/MS should be generated.

### Examples of PCR-MS and PCR-MS-MS Analyses for Genetic Analysis

Regardless of the source of a PCR product, e.g., human, plant, or microbe, sample preparation is identical and the final product is an MS or MS/MS spectrum. Certain complex samples, e.g., environmental samples, contain inhibitors of the PCR reaction (e.g., humic acids and metal ions) and developments in this area are continuing which are beyond the scope of this article. The examples below are only provided to illustrate what can be achieved with PCR-MS or MS/MS analysis.

### Chemotaxonomic Differentiation of Bacteria

Due to the nature of PCR, this can be accomplished either directly from clinical or environmental samples or after culture. However, since environmental samples contain numerous bacterial species, among which bacilli are the most common, design of primers is important since otherwise complex mixtures of PCR products would be generated. Such mixtures would be extremely difficult to analyze by direct MS analysis. Furthermore, sensitivity of analysis would be compromised by spreading the signal among numerous components. Indeed, successful analysis directly from environmental samples is still a topic for current research.

As an example of bacterial discrimination, using pure bacterial cultures, the ribosomal RNA (*rrn*) operon consists of 16S and 23S rRNA genes flanking an interspace region (ISR). This operon is present in all bacteria but the sequence varies among bacteria in a species-specific fashion. For example, variation in ISR size readily distinguishes the *B. cereus* group of organisms (which includes *Bacillus anthracis*, *B. cereus*, and *B. thuringiensis*) from the closely related *B. subtilis* group (which includes *B. subtilis* and *B. atrophaeus*) (Figure 2). With appropriate primers, 89 bp products are generated for the former and 111–119 bp products for the latter. Based on sequencing of single operons, until recently, it was felt that *B. anthracis* and *B. cereus/B. thuringiensis* were identical in all regions of the *rrn* operon. However, work from the Centers for Disease Control comparing sequences of the 11 operons of the 16S rRNA gene in the *B. anthracis* genome, at position 1146, revealed five genes contain Ts whereas six contain As. However, for *B. cereus* and *B. thuringiensis* only Ts were observed at this position. It is demonstrated here that MS has the discriminating power to detect such fine genetic differences (an A to T switch) (Figure 3). Synthetic oligonucleotides, having the same sequence as the bacterial genes, were used. Thus, further work will be needed to develop a routine procedure utilizing PCR products.

Unfortunately, the ability to detect small genetic changes becomes more difficult as mass increases. Thus, there is an upper mass range where analysis is impractical. For low-resolution instruments, this limit is around a 100-mer. Thus, the mass should be minimized (or a high-resolution instrument employed). Alternatively, the smaller the piece of DNA analyzed the more it chemically resembles a primer or nucleotide monomer; thus, separation of the two on cleanup becomes more difficult. If the primers and nucleotides are not removed, they can provide a massive background on MS analysis or inhibit ion-

**Figure 3** Measured MW of four synthetic oligonucleotides (39-mers) determined using ESI-quadrupole MS. The sequences correspond to two regions of the *B. anthracis* genome coding for 16S rRNA and differing by a single nucleotide substitution at one position (A to T switch). Predicted mass of noncoding strands: 11,967.8 and 11,976.8; and coding strands: 11,993.8 and 12,002.8, respectively.

ization of the PCR product by preferential ionization. Thus, for practical reasons, it is extremely difficult to employ a PCR product below a 40–50-mer for direct ESI MS or ESI MS/MS analysis.

### Human Genomics and Cancer Diagnostics

Mutations in the oncogene *K-ras* can occur at positions one or two of codon 12. Thus, at each of two adjacent positions, there can be variation from G to C, A or T (six in total). It has been suggested that knowing the exact mutation could have important diagnostic or therapeutic implications for certain forms of cancer. Variations at position one are single nucleotide substitutions, and changes at position one versus complementary changes at position two constitute isomeric changes. In the latter case, the mass is the same and MS/MS is required for discrimination of genetic variants (Figure 4).

Although 50–100-mers have been sequenced, interpretation of fragmentation patterns of large pieces of DNA still remains challenging at the present time. Indeed, for complete sequence information, PCR products must currently be <80-mers in length, even

**Figure 4** Discrimination of isomeric PCR products using tandem mass spectrometry. Two mutant sequences of regions of the *K-ras* gene are shown that have the same base composition (due to sequence change at two adjacent positions within a codon) and thus the same mass on MS analysis. However, scission within this codon, on MS–MS analysis, generates two fragments for each respectively differing in sequence and mass.

with the assistance of advanced computer software. In diagnostic applications or studies of population diversity, the sequence difference between normal and cancer DNA or between genes of two individuals is determined; the rest of the sequence is identical.

Algorithms have also been developed that use automated software to compare product ion spectra (abundances of each fragment ion) of PCR products displaying single nucleotide polymorphisms or isomeric sequence changes. To find the reference sequence most closely related to the experimental spectrum, the algorithm replaces each nucleotide by the other three possible nucleotides, and determines the best fit. More simply, relative abundances of specific fragment ions, for the discrimination of closely related PCR products of different structure, are directly compared for similarities or differences. In this simple comparison of mass spectral patterns, interpretation is not necessary. All that is required is finding a single MS/MS peak that occurs in one genetic variant but not in another. Unfortunately, MS/MS spectra are extremely complex and visual discrimination is extremely time consuming and, in some cases, impossible. In order to automate this process, a new computer algorithm, SpecDiff, was recently created that automatically compares spectra searching for such differences (<http://fields.scripps.edu/SpecDiff>).

### Future Directions

There is great potential for integration of all stages of PCR–MS and PCR–MS/MS analysis including sample collection, DNA isolation, PCR, sample cleanup, MS/MS, and computer-assisted data handling. As noted above, with the exception of sample clean-up, the other stages are identical for real-time PCR and

PCR–MS. However, PCR–MS and MS/MS provide a great deal of additional structure information. This is absolutely required in detection of a specific genetic variant (for genotyping or forensic analysis) of a human or bacterial cell or detection of a particular bacterial species (e.g., *B. anthracis*) in a complex clinical or environmental matrix.

The availability of integrated commercial instrumentation could be of immeasurable benefit to biomedical science and homeland security. For human genotyping, MS and MS/MS represent a powerful approach for defining genetic variation. In forensics, the fine discriminating power might be used to define the origin of particular bacterial or viral strain. A particularly difficult analytical problem remains detection of a bioterrorist attack. The specificity of MS/MS analysis could be of major importance in solving the problems of false positives, which is of much greater concern for environmental than clinical analysis, due to the complexity of the microbial population in the latter.

### Introduction

Dialysis is a separation process with many applications in clinical, biochemical, and environmental

analysis. Donor and acceptor solutions are separated by a membrane, which is permeable to one or more solutes. When the solutions have different solute activities, a diffusional transport from the higher to the lower activity  $a$  ( $a = cf$ , where  $c$  is the concentration and  $f$  the activity coefficient) through the membrane takes place (**Figure 1**). The main driving force for the diffusion of small molecules or ions is their concentration gradient. In most cases, dialysis is employed to retain large molecules while exchanging or eliminating small ones.

Different solvent activities generate an osmotic pressure, which causes a solvent flow to the solution

### Introduction

Dialysis is a separation process with many applications in clinical, biochemical, and environmental

analysis. Donor and acceptor solutions are separated by a membrane, which is permeable to one or more solutes. When the solutions have different solute activities, a diffusional transport from the higher to the lower activity  $a$  ( $a = cf$ , where  $c$  is the concentration and  $f$  the activity coefficient) through the membrane takes place (**Figure 1**). The main driving force for the diffusion of small molecules or ions is their concentration gradient. In most cases, dialysis is employed to retain large molecules while exchanging or eliminating small ones.

Different solvent activities generate an osmotic pressure, which causes a solvent flow to the solution

**Figure 1** Dialysis between quiescent (I) and stirred or flowing solutions (II) solutions. C, concentration; D, donor solution; A, acceptor solution; M, membrane;  $d_M$ , thickness of the membrane;  $\delta_A$  and  $\delta_D$ , thicknesses of the boundary layers.

of the lower solvent activity. This process is termed osmosis. Reverse osmosis is the process during which an outer pressure is applied to force the solvent through a membrane, which rejects the solute. Reverse osmosis is used almost exclusively to desalt and purify water. In the ideal case, the separation membrane is only permeable to water.

## Thermodynamics

The difference between the chemical activities of the solute  $i$  is the precaution for its diffusional transport through the separation membrane. The free enthalpy  $\Delta G$  of diffusion can be calculated from the difference between the chemical potentials  $\mu_{i,A}$  and  $\mu_{i,D}$  of the solute  $i$  in the acceptor (A) and donor solution (D), respectively (eqn [1]).  $\mu_{i,D}^0$  and  $\mu_{i,A}^0$  are the standard chemical potentials,

$$\Delta G = \mu_{i,D} - \mu_{i,A} = \mu_{i,D}^0 - \mu_{i,A}^0 + RT \ln(a_{i,D}/a_{i,A}) \quad [1]$$

The equilibrium constant  $K_i^*$  depends on the activity coefficients  $f_{i,A}$  and  $f_{i,D}$ , the concentrations  $c_{i,A}$  and  $c_{i,D}$ , and the absolute temperature  $T$  according to eqn [2].  $R$  is the molar gas constant.  $K_i^*$  is given as

$$K_i^* = \frac{a_{i,A}}{a_{i,D}} = \frac{f_{i,A} \times c_{i,A}}{f_{i,D} \times c_{i,D}} = \exp \left[ \frac{\mu_{i,D}^0 - \mu_{i,A}^0}{RT} \right] \quad [2]$$

The effective separation ratio  $K_i$  is calculated according to eqn [3]

$$K_i = \frac{c_{i,A}}{c_{i,D}} \quad [3]$$

At  $K_i^* = 1$  a stationary state, called the thermodynamic equilibrium is reached and no directed diffusion can take place.  $K_i$  differs from unity when the activity coefficients of the solute  $i$  are different, e.g., if the donor and acceptor solutions have different compositions and/or the dialysis equilibrium is coupled with other equilibria. Without coupled reactions, the enrichment  $E$  and the purification  $P$  can be calculated according to eqns [4] and [5],

$$E = \frac{c_{i,A}}{c_{i,D_0}} = \frac{(c_{i,D_0} - c_{i,D})V_D}{c_{i,D_0} \times V_A} \quad [4]$$

$$P = \frac{c_{i,D_0} - c_{i,D}}{c_{i,D_0}} = \frac{(c_{i,A} - c_{i,A_0})V_A}{c_{i,D_0} \times V_D} \quad [5]$$

where  $c_{i,D_0}$  and  $c_{i,A_0}$  are the initial solute concentrations in the donor and in the acceptor solution, respectively.  $V_A$  and  $V_D$  are the volumes of the corresponding solutions. Without trapping reaction in the acceptor solution, during which the received analyte is converted into a substance that cannot permeate the membrane, the enrichment  $E$  approaches 0.5 for  $V_A = V_D$ . If the activity coefficients are equal (i.e.,  $f_{i,A} = f_{i,D}$ ) in the equilibrium state,  $E$  will be 0.5. Also the chemical activities of the solvent  $S$  are equal at dialysis equilibrium. Because

$$\mu_{S,D} = \mu_{S,A} \quad [6]$$

and

$$\mu_{S,D}^0 = \mu_{S,A}^0 \quad [7]$$

The thermodynamic equilibrium constant  $K_S^*$  is given as

$$K_S^* = \exp[(V_{mS,D}\pi_D - V_{mS,A}\pi_A)/RT] = \frac{a_{x,S,A}}{a_{x,S,D}} \quad [8]$$

where  $V_{mS,D}$  and  $V_{mS,A}$  are the partial molar volumes of the solvent, which are equal to the  $V_{mS}$  for dilute solutions.  $\pi_D$  and  $\pi_A$  refer to the corresponding osmotic pressures.  $a_{x,S,A}$  and  $a_{x,S,D}$  are the activities of the solvent with respect to its mole fraction  $x_S$  in the acceptor and donor solutions, respectively. It follows that

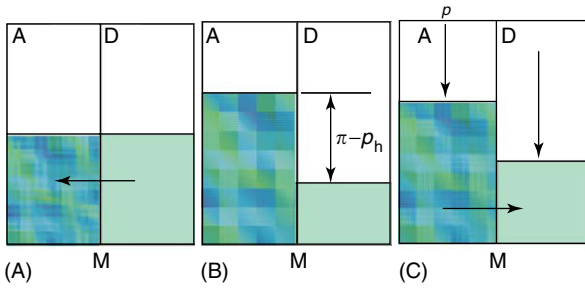

$$K_S^* = \exp[(\pi_D - \pi_A)V_{mS}/RT] \quad [9]$$

The resulting pressure difference  $\pi = \pi_D - \pi_A$  can be calculated according to eqn [10]:

$$\pi = -(RT/V_{mS}) \ln a_{x,S,A} \quad \text{for } a_{x,S,D} = 1 \quad [10]$$

This pressure difference causes a solvent flow through the separation membrane (Figure 2A) up

**Figure 2** (A) Osmosis; (B) osmotic equilibrium; (C) reverse osmosis. M, semipermeable membrane;  $p_h$ , hydrostatic pressure;  $\pi$ , osmotic pressure;  $p$ , external pressure, D, aqueous salt solution, A, water.

**Figure 3** Donnan dialysis. M, semipermeable membrane; D, donor solution; A, acceptor solution,  $\phi$ , Donnan potential;  $U$  applied voltage.

to the state at which the hydrostatic or another back-pressure compensates for the osmotic pressure, e.g., in batch-type arrangement shown in **Figure 2B**. If the outer pressure  $p$  is higher than the osmotic pressure difference  $\pi$ , the osmosis will be reversed (**Figure 2C**). An equilibrium described by eqn [11] will be reached:

$$K_S = \exp \left[ \frac{V_{mS}}{RT} (\pi - p_h) \right] \quad [11]$$

The rejected solute is enriched in the donor solution. To take into account the electric charge  $z_i$  of the solutes and of the separation membrane, the Donnan effect has to be considered. The chemical potential  $\mu_i$  is extended by the electric potential gradient,  $\Delta\phi$ . When a membrane separates two solutions of a dissociating salt  $BA$  ( $BA \rightleftharpoons B^+ + A^-$ ), one of which contains a rejected ion  $X^-$ , an electric potential difference  $\Delta\phi = \phi_D - \phi_A$  is built up between the solutions (**Figure 3**). The thermodynamic equilibrium constant can be calculated in the absence of osmotic pressure differences according to eqn [12] with the

Faraday constant  $F$ :

$$K_i^* = \exp(z_i F \Delta\phi / RT) \quad [12]$$

An additionally applied electric voltage  $U$  generates an electromigration of the anions to the positively charged anode and of the cations in the opposite direction. This process is termed electrodialysis.

## Mass Transport

### Dialysis

For quiescent donor and acceptor solutions, the equilibration time ranges from minutes to several hours and is dependent on the thickness and other geometrical parameters of the corresponding chambers, the membrane permeability, and the temperature. The equilibration is dominated by diffusion. The equilibration can be accelerated by convective mass transport according to **Figure 1** by achieving thin diffusional boundary layers on the membrane.

The overall flux of the substance  $i$  with its molar amount  $n_i$  from the donor to the acceptor solution can be described according to eqn [13]:

$$J_i = \frac{dn_i}{dt} = kA \left( \beta_{i,D} c_{i,D} - \beta_{i,A} c_{i,A} \frac{K_{AM}}{K_{DM}} \right) \quad [13]$$

where  $\beta_{i,D}$  and  $\beta_{i,A}$  are the fractions of the substance  $i$  in the donor and in the acceptor solutions, respectively, that can permeate through the separation membrane.  $K_{DM}$  and  $K_{AM}$  are the distribution constants between the donor solution and the membrane and between the acceptor solution and the membrane, respectively. In the classical case of dialysis of low molecular substances through a membrane with symmetric and open pores eqn [14] holds

$$J_i = \frac{dn_i}{dt} = kA (c_{i,D} - c_{i,A}) \quad [14]$$

The general overall mass transfer coefficient  $k$  can be derived from eqn [15]

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M K_{DM}} + \frac{K_{AM}}{k_A K_{DM}} \quad [15]$$

where  $k_D$ ,  $k_M$ , and  $k_A$  are the mass transfer coefficients of the permeating fractions of substance  $i$  for the donor, the membrane, and the acceptor phases, respectively. In many cases, the mass transfer across the phase boundary also needs to be considered, e.g., for gas-filled microporous membranes. Equation [16] has an additional term on the right-hand side:

$$a = \frac{1}{k_{pDM}} + \frac{1}{k_{pAM}} \frac{K_{AM}}{K_{DM}} \quad [16]$$

where  $k_{pDM}$  and  $k_{pAM}$  are the phase transfer coefficients from the donor solution into the membrane phase and from the membrane into the acceptor phase, respectively.

From the general eqns [15] and [16], some cases of practical interest can be deduced.

**Dialysis through hydrophilic and microporous membranes** As  $K_{DM} = K_{AM} = 1$  and no phase transfer occurs, eqn [15] simplifies to eqn [17] as follows:

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M} + \frac{1}{k_A} \quad [17]$$

For large concentration gradients and very intensive stirring or in flow-through dialysis cells at high enough flow rates, the membrane diffusional transport becomes rate determining particularly for relatively thick membranes with small pores (eqn [18])

$$k = k_m \quad [18]$$

**Dialysis of volatile and volatilizing substances through hydrophobic and microporous membranes** To separate a nonvolatile base  $AH^+$ , its corresponding volatile base  $A$ , e.g.,  $NH_3$  is produced according to the following equilibrium:

The donor pH value is adjusted according to eqn [20] so that there is 99.9% degree of conversion into the volatile and the permeable base:

$$\beta_{i,D} = \frac{K_a}{10^{-pH} + K_a} > 0.999 \quad [20]$$

where  $K_a$  is the acid-dissociation constant of  $AH^+$ . The acceptor pH value should be adjusted according to eqn [21] to trap the analyte in its nonvolatile form:

$$1 - \beta_{i,A} = \frac{10^{-pH}}{10^{-pH} + K_a} > 0.999 \quad [21]$$

Analogous equations can be derived for volatile acids, e.g.,  $HCN$ . Since only the volatile part of the analyte amount permeates the membrane, it follows that

$$J_i = kA c_{i,D} \quad [22]$$

with

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{K_M K_{DM}} + \frac{K_{AM}}{K_A K_{DM}} + a \quad [23]$$

The distribution ratios  $K_{DM}$  and  $K_{AM}$  are inversely proportional to the concentrations  $\beta_{i,D} \times c_{i,D}$  and  $\beta_{i,A} \times c_{i,A}$  of the volatile forms in the donor and in

the acceptor solutions, respectively:

$$K_{DM} = \frac{c_{i,g,D}}{\beta_{i,D} \times c_{i,D}} \cong \frac{p_{i,D}}{\beta_{i,D} RT c_{i,D}} \quad [24]$$

$$K_{AM} = \frac{c_{i,g,A}}{\beta_{i,A} \times c_{i,A}} \cong \frac{p_{i,A}}{\beta_{i,A} RT c_{i,A}} \quad [25]$$

For low partial pressures  $p_{i,D}$  and  $p_{i,A}$ ,  $K_{DM}$  and  $K_{AM}$  approximate the right-hand terms of eqns [24] and [25].  $c_{i,g,D}$  and  $c_{i,g,A}$  are the gas-phase concentrations at the interface between the donor or the acceptor solution and the membrane gas phase, respectively. Because the nonvolatile forms of the analyte cannot permeate and  $K_{AM}$  approximates zero at pH precalculated by eqn [21]. Equation [15] simplifies to eqn [26] as follows:

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M K_{DM}} + a \quad [26]$$

For fast-flowing donor solutions with  $1/k_D \rightarrow 0$  the mass transport is determined by the gas diffusion through the membrane, the partial pressure of the analyte in the donor solution, and the phase-transfer resistances.

### Reverse Osmosis

The driving force of reverse osmosis is the difference between the outer pressure  $p_h$  and the osmotic pressure difference  $\pi$ . The mass transfer can be described according to the following equation:

$$J_s = n_s/t = PA(p_h - f_R \pi) \quad [27]$$

where  $J_s$ ,  $P$ , and  $A$  are the mass flux of the solvent through the separation membrane, the water permeability of the membrane, and the membrane area, respectively. The mass flux is influenced by the reflection factor  $f_R$ , which is a measure of the solute rejection by the membrane. The osmotic pressure difference increases continuously during the enrichment of the solutes in the donor solution up to  $p_h = f_R \pi$ . The rejection ratio  $R$  is defined by eqn [28]:

$$R = 1 - \frac{c_{i,A}}{c_{i,D,o}} \quad [28]$$

with  $c_{i,A}$  as the solute concentration in the filtrate, and  $c_{i,D,o}$  as the initial concentration in the donor solution. The rejected solutes accumulate on the membrane surface (Figure 4). This phenomenon is called concentration polarization. On achieving the saturation level, the solute will start to precipitate forming a secondary layer on the membrane, which drastically reduces the mass flux through it. The analytical usefulness of the reverse osmosis is based on the high enrichment factor  $E$ , which can be

**Figure 4** Reverse osmosis with concentration polarization on the asymmetric separation membrane.  $J_i$ , mass flux of the solute  $i$ ;  $p_D$ , outer pressure from the donor side;  $p_A$ , outer pressure from the acceptor side;  $\pi_A$  and  $\pi_D$ , osmotic pressure in the acceptor and donor chamber, respectively;  $d_M$  and  $d_S$ , thickness of the membrane layer and the membrane supporting layer, respectively;  $\delta_C$ , thickness of the polarization layer;  $c_{i,DM}$ ,  $c_{i,A}$ ,  $c_{i,D}$ , concentration of the solute  $i$  in the acceptor solution, in the donor solution, and at the separation membrane, respectively.

calculated according to eqn [29]:

$$E = \frac{c_{i,D}}{c_{i,D0}} = \frac{V_{D,o}}{V_{D,o} - V_A} \quad [29]$$

where  $V_{D,o}$  is the initial volume of the donor solution.

### Geometric Aspects

The geometric shape and volume both of the donor and the acceptor chambers as well as of the separation membrane have an essential influence on the duration of the separation. To minimize the separation time, the thickness of the donor solution layer should be as thin as possible. The ratio of the membrane exchange area to the donor solution volume should be maximized. To maximize the enrichment factor for dialysis with enhanced selectivity, e.g., gas dialysis, the volume ratio between the donor solution and the acceptor solution has to be maximized. The miniaturization of the membrane exchange area up to the micro- or the ultramicroscale enables reproducible sampling from quiescent or slowly flowing solutions to be performed. This is an essential aspect for *in vivo* sampling with microdialytic probes. Figure 5 shows frequently used hollow-fiber and flat-membrane setups.

### The Separation Membrane

The dialytic transport of solute  $i$  through thin membranes can be described by eqn [30]:

$$J_i = \frac{dn_i}{dt} = k_{MA}(c_{i,MD} - c_{i,MA}) \quad [30]$$

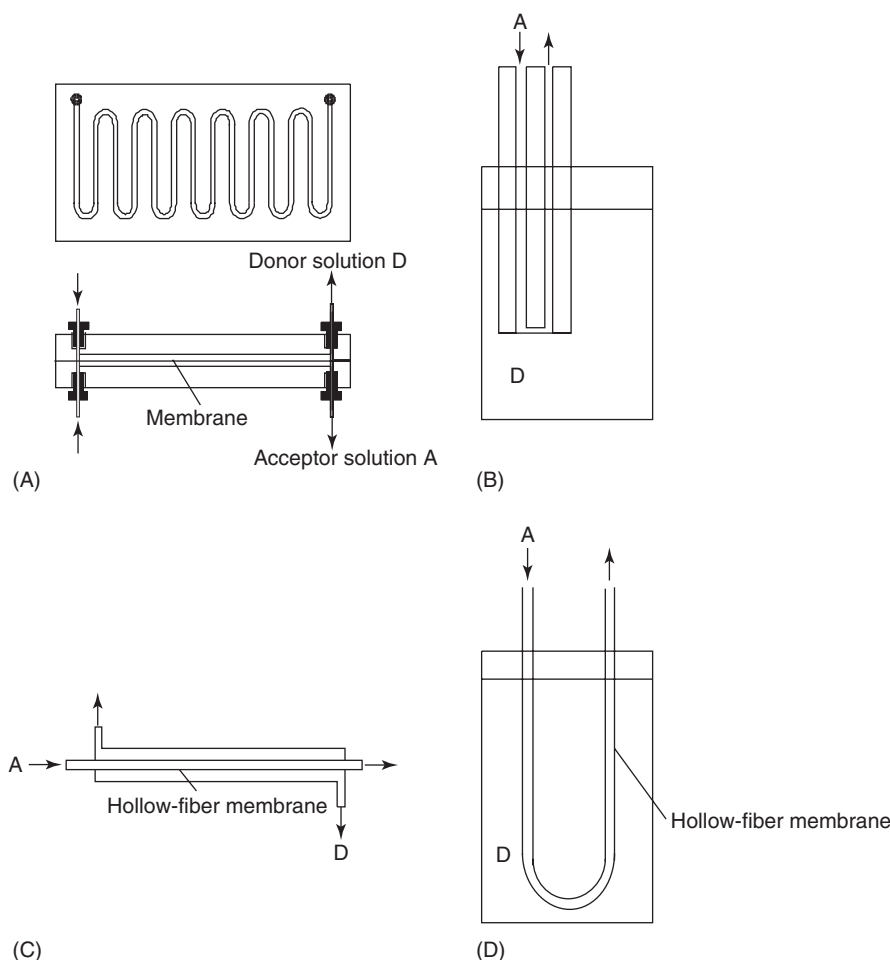

where  $c_{i,MD}$  and  $c_{i,MA}$  are the solute concentrations in the membrane at the interfaces between donor and acceptor solutions, respectively. The separation membrane is chosen with respect to its selectivity and mass transfer kinetics. The membrane material determines the transport mechanism. Table 1 gives an overview about membrane materials, their modifications, and the dominant transport mechanism. In most cases the selectivity is based on the sieve effect of the membrane pores. The dialysis across gas-filled membranes, ion-exchange membranes, or supported liquid membranes (SLMs), the pores of which are filled with organic solvents or solvent mixtures with and without additives, enables the enrichment of the analyte to be detected. The selectivity of SLM techniques is enhanced by the addition of selectively reacting ligands to the liquid membrane phase. When charged ions are complexed and transported through such membranes electroneutrality must be maintained. In some cases ion pairs with selected counterions are transported through the liquid membrane phase. When a binding ligand is dissolved in this phase and the counterion cannot transverse the membrane, the analyte ion transport is coupled with back-diffusion of an ion from the acceptor solution. A similar situation occurs in ion-exchange membranes, which are used to enrich ions by Donnan dialysis.

Using microporous membranes with a hydrophobic inner surface, the selectivity of gas dialysis against other volatiles results predominately from the ratio of the partial pressure of the analyte  $p_i$  to the total pressure. In homogeneous membranes, the different solubilities of the gases in the membrane material are the main selecting factor.

## Applications

### Dialysis through Microporous Membranes

In analytical chemistry this kind of dialysis is applied for purifying, diluting, and conditioning the sample solutions. The dialysis module can be placed prior to or in the sample insertion unit, between the sample insertion unit and the reaction/separation zone and also into the detector zone. Figure 5A shows a typical flow dialysis cell, which can be inserted in many on-line configurations with liquid chromatography and flow injection analysis (FIA), as shown in Figure 6. Two meander channels (depth:  $d = 0.1\text{--}0.5\text{ mm}$ , width:  $b = 1\text{--}2\text{ mm}$ ) are separated by a membrane. The main advantages are: easy exchange of the membrane and the use of very different membrane materials. In a second version of dialysis cell (Figure 5B) a hollow-fiber membrane is concentrically placed

**Figure 5** Frequently applied dialysis setups. (A) Thin layer flow cell, (B) immersion membrane probe, (C) hollow-fiber membrane module, and (D) immersing hollow-fiber membrane probe.

**Table 1** Membrane transport and selectivity

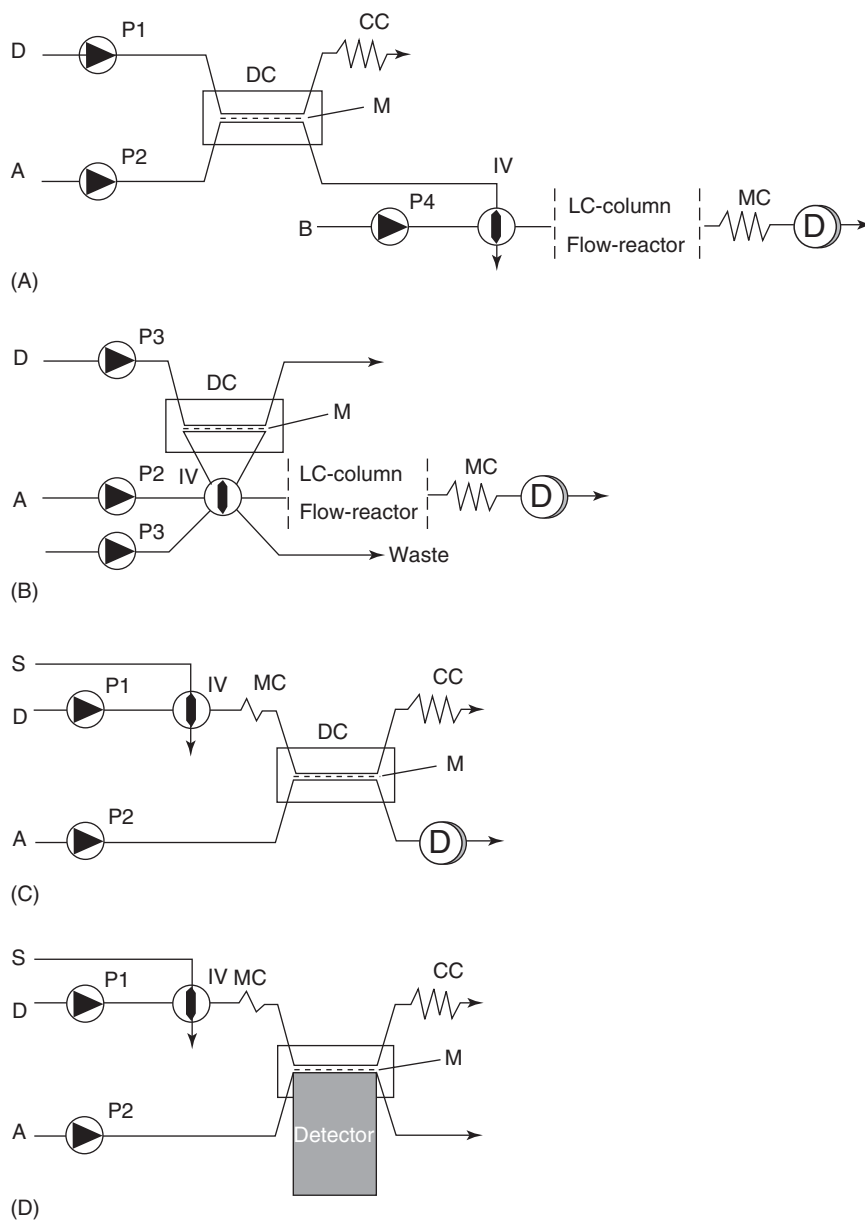

Membrane material	Transport mechanism	Factors determining selectivity
Hydrophilic and electrically uncharged	Diffusion through micropores ( $k_M = D_m \epsilon / \xi d_M$ )	Sieve effect
Ion-exchange membranes	Retarded diffusion through micropores	Ion exchange, Donnan exclusion
Hydrophobic and microporous	Gas diffusion and flow	Volatility
As before but filled with organic solvent phase with and without reactants	Diffusion through Micropores	Solubility and chemical reaction
Homogeneous membranes	Solvation and diffusion	Solubility in the membrane

$D_m$ , molecular diffusion coefficient;  $\epsilon$ , membrane porosity;  $\xi$ , tortuosity of the pores;  $d_M$ , thickness of the membrane.

inside a tube forming a thin-layer acceptor chamber. Higher mass transfer efficiencies are achieved with respect to the membrane area. There is a growing interest in dialysis immersion probes working either with a small membrane window or a hollow-fiber membrane (Figures 5C and 5D). Immersion dialysis probes with integrated sensors, e.g., biosensors open up a way to adapt the sample solution to the sensor with respect to the determination range and the

conditions of detection. The sensor can be calibrated *in situ* by pumping standard solutions through the immersion probe.

Figure 6 shows typical online dialysis configurations. A continuously working dialysis cell can be coupled directly to the valve IV (Figure 6A) injecting the prepurified and conditioned sample solution into a nonsegmented carrier flow stream, e.g., of liquid column chromatography. The analytes are separated

from high molecular weight substances, e.g., proteins or from precipitates and microparticles. Blocking of the separation column is prevented and its life time is prolonged. To improve the sensitivity, the transferred amount of the analyte can be increased by the loop-dialysis setup shown in **Figure 6B**. The analyte is accumulated in the acceptor loop followed by injection into the detector channel D. To reduce the contact time of sample solution with the separation membrane, the setup shown in **Figure 6C** is used. The probability of membrane fouling and clogging is decreased considerably. A dialysis cell (**Figure 6D**) with

integrated detector can be used to increase the sensitivity and to shorten the analysis time.

A very promising and even more expanding field of application was opened up more than 15 years ago by the microdialysis technique, which is the most widely used dialysis technique in bioanalytical and clinical chemistry. The main advantages are: *in situ* sampling, *in situ* calibration, and avoiding the influence of complex samples matrices on to the indicator reaction. **Table 2** summarizes the application areas. Miniaturized dialysis probes with tip diameters smaller than 1 mm are implanted into different

tissues of living animals for sampling low molecular weight substances from the interstitial fluid. The analyte is separated across small membrane windows, e.g., of microporous cellulose acetate and polysulfone membranes with cutoffs between 1000 and 60 000 Da into a slowly flowing acceptor stream. The microdialysis probes are coupled online to micro-column LC systems, to capillary FIA setups and to capillary electrophoresis devices. **Figures 7A** and **7B** show a simple microdialysis probe and a probe with integrated amperometric detection, respectively. In the latter version, an enzyme solution can be used to catalyze a reaction generating a substance, e.g.,  $\text{H}_2\text{O}_2$  or an oxidized redox mediator, which can be detected selectively and sensitively. Much shorter response times are achieved in comparison to the on-line coupling to external analytical setups. According to Hamberger *et al.* (1991) the solute concentration  $c_{\text{out}}$  at the outlet of microdialysis probes can be calculated with eqn [31] with the sample concentration  $c$ , the membrane area  $A$ , the volumetric flow rate  $v$  and the overall mass transfer coefficient  $k$ , which depends on the mass transport resistances in the sample tissue, the membrane, and the dialysate.

$$c_{\text{out}} = c(1 - \exp[-kA/v]) \quad [31]$$

### Selective Dialysis across Solid and Liquid Membranes

The analyte transport through such membranes is based on a solvation/diffusion mechanism in a lipophilic phase. The liquid membranes have to be supported by a microporous and hydrophobic layer. The flow separation cells shown in **Figure 5** can be used to apply these membranes for separation procedures that can be coupled online to flow analytical, liquid, and gas chromatographic setups.

In comparison to homogeneous membranes, e.g., of silicon rubber, the SLMs have the advantages of faster membrane diffusion, and easier and wider modification of the liquid phase, which determines the transport mechanism and the selectivity. Further advantages are the low amount of organic solvent and of extractants, low operating costs, easy automation, and high enrichment factors. Dialysis across SLMs has a wide and continuously growing field of application in environmental analysis. **Table 3** summarizes some applications. Three modes of separation are used:

1. An electrical neutral substance diffuses from the donor solution through the liquid membrane phase into the acceptor solution.

- The analyte is converted into a membrane soluble substance by pH shift or chemical reaction, which diffuses through the membrane and is trapped as a substance that is insoluble in the membrane.
- Co-ion-mediated transport on the basis of a carrier substance, which is dissolved in the liquid-membrane phase. The carrier molecule takes up the analyte molecules or ions, whereby a hydrophobic complex or an ion-pair is formed.

## Gas Dialysis

Gas dialysis is based on the diffusion of a volatile solute from the donor solution through a gas-filled membrane or a membrane in which the volatile substance is soluble, into an acceptor solution.

By trapping a volatile analyte as a nonvolatile form these substances can strongly be enriched. Gas dialysis is used in FIA procedures and other flow-analytical methods to enhance their selectivity for volatile substances or substances, which can be converted into volatiles. The configurations shown in **Figures 5A–5D** are used and adapted. **Table 4** summarizes the applications of the gas dialysis technique. Several nonvolatile species, e.g., acetates can be separated after acidification. Gas dialysis membranes can

separate aqueous solutions with very different pH values and ionic strengths, which enables extreme samples also to be adapted to primarily unsuitable detection procedures. Microporous polytetrafluoroethylene or polypropylene membranes are used in most cases. However, it should be noted that, for example, surfactants and many water-soluble organic compounds adsorb on the membrane surface, which then becomes increasingly hydrophilized. In some of such situations, homogeneous membranes, e.g., silicon-rubber membranes can be advantageous. It should be noted, that silicon-rubber membranes are permeable to hydrogen sulfide, hydrogen cyanide, carbon dioxide, and many organic volatiles and they also have higher selectivity against other hydrophilic gases, e.g., NH<sub>3</sub> and SO<sub>2</sub> in comparison to microporous membranes with a hydrophobic inner surface.

## Reverse Osmosis

Despite its advantages, reverse osmosis is seldom used in analytical procedures. However, diluted sample solutions can be concentrated. Not only high molecular weight substances, but also low molecular weight substances, are rejected by ultrafiltration

membranes. The typical application of reverse osmosis is the separation of low molecular weight substances from aqueous solutions to purify water or to concentrate the substances that are to be determined. The water is propelled by a relatively high pressure gradient through a membrane, which is permeable to water but rejects dissolved molecules and ions. Bundles of hollow-fiber membranes are used in most technical applications, e.g., to desalt seawater.

Highly diluted sample solutions can be concentrated to analyte concentrations, which can be determined by the available determination method. The analyte can theoretically be concentrated up to the precipitation level. Then an additional filter layer is used, which is exchanged and directly analysed, e.g., by X-ray fluorescence spectrometry. For example, transition metals could be analysed in drinking water up to the micrograms per liter level.

## Introduction

The use of ultrafiltration (UF), microfiltration (MF), and other filtration techniques using semipermeable

membranes enable separation that cannot be performed using other means. Membrane-based size fractionation is useful for determination of the distribution pattern of trace elements in natural waters and other fluids. Elements associated with suspended particles, colloids, and polymers as well as the ionic forms of these elements can be determined separately after membrane filtration separation and preconcentration. The possibility of preconcentration and separation of different species without using separating agents is another advantage of some membrane techniques. This is of particular interest in trace and ultratrace analysis to decrease the chance of contamination and in biological and clinical assays, where particles to be analyzed should not suffer changes during prepreparation.

Separation using UF and MF membranes is most selective, however, if soluble reagents are added. Such techniques may supplement two-phase distribution methods (e.g., liquid–liquid extraction, sorption, and precipitation), which are frequently used to extract species from dissolved matrices, industrial fluids, or natural waters. Although many such methods have been developed and successfully used, their application is sometimes troublesome. Some problems are caused by heterogeneous reactions and transfer between phases. Other problems can arise from the composition of the solution finally obtained, which is analyzed using the final determination method. In such cases, additional procedures may be required, e.g., back-extraction or desorption, which make the analytical procedure more complex and can cause additional contamination. Membrane separation can yield a homogeneous aqueous phase suitable for subsequent analysis using a number of methods.

## Principles

UF and MF are pressure-driven membrane transport processes used to separate macromolecules, colloids, microorganisms, and solid particles from fluids. Generally MF refers to processes used to remove particles greater than 0.5  $\mu\text{m}$ . For UF of macromolecules and colloidal particles, membrane filters of 0.002–0.5  $\mu\text{m}$  pore size are available. The membranes are necessary to filter viruses (0.03–1  $\mu\text{m}$ ) and bacteria (0.5–20  $\mu\text{m}$ ). Size cutoffs for MF are usually expressed in terms of micrometers, while UF cutoffs are often expressed in terms of molecular mass.

The first systematic study of UF was undertaken by Bechhold in 1907. Applications of UF are found in the food, drug, chemical, water, and wastewater treatment industries. The major use of MF is probably in sterile filtration. During the last 30–40 years

UF and MF have been successfully employed in analytical chemistry. The principal factors that should be considered for analytical and technological use of membranes with aqueous media are the pore size and pore size distribution, solution flow, and degree of hydrophilicity. The solution flow (flux) through an MF or UF membrane is given by the equation  $J = P/R$ , where  $J$  is the solution flux,  $R$  is a phenomenological resistance coefficient, and  $P$  is the transmembrane pressure drop. A pump or a gas (e.g., nitrogen) bottle can be used as a pressure source (50–500 kPa). The other main features of the filtration system are a membrane filtration unit and reservoirs.

## Membranes and Equipment

Flat-sheet asymmetric-skinned membranes made from synthetic polymers (also copolymers and blends), track-etched polymer membranes, inorganic membranes with inorganic porous supports and inorganic colloids such as  $\text{ZrO}_2$  or alumina with appropriate binders, and melt-spun ‘thermal inversion’ membranes (e.g., hollow-fiber membranes) are in current use. The great majority of analytically important UF membranes belong to the first type. They are usually made of polycarbonate, cellulose (esters), polyamide, polysulfone, poly(ethylene terephthalate), etc.

The pore size distribution in the membranes is another factor that may influence the reliability of membrane separations. Membranes with a relatively narrow distribution are produced. For example, the pore size distribution in some MF Millipore membranes are 0.025–0.05, 0.1–0.22, 0.45–0.65, 1.2–3.0, and 5.0–8.0  $\mu\text{m}$ . High uniformity of the pore size is attained in plastic track-etched (nucleoporous) filters, prepared by bombardment with high-energy heavy ions in cyclotrons with subsequent etching using an alkali solution. Since the open area is often low (0.1–1% of the surface), the housing geometries for membranes are designed to ensure high total areas and low feed pressures.

The so-called hollow-fiber modules meet some of these requirements. A hollow-fiber module consists of a large number of hollow fibers cemented on both ends to the module housing. The fibers may be some 500–1500  $\mu\text{m}$  in diameter, and they are formed of a self-supporting UF membrane.

Membranes are subject to concentration polarization. During UF, the solute accumulates at the membrane surface and the actual concentration may be much higher than that which corresponds to the bulk concentration. This process is called concentration polarization of the membrane. It can be minimized by use of stirred filtration cells or cross-flow units. In

standard stirred cells the liquid flow is parallel to the direction of applied pressure. In this case particles and large molecules may block the pores. Cross-flow or tangential-flow filtration units, where the liquid flow is in a narrow gap between two filters, are currently used. Such units enable faster filtration without blinding the filters as the accumulated solute is swept by the flow parallel to the membrane surface.

Membrane fouling is caused by capture of particles or formation of a gel-like layer on the membrane and the resultant decrease in the area available for fluid flow. Prefiltration, pH adjustment, or other means may be used to prevent fouling.

In multistage separations, minimization of concentration polarization, membrane fouling, and loss of separated components, which can occur in cascades of stirred cells or hollow-fiber modules due to the use of relatively lengthy tubing and a number of connectors and valves, is achieved by using an online multistage membrane filtration device (OMFD). The device consists of several disks coupled together in which different membranes with pore size from  $8\text{ }\mu\text{m}$  to  $1\text{ kDa}$  are inserted (Figure 1). The disks have fine channels on the upper part and a drainage system connected with the under-membrane space of the next disk in the lower part. The sample solution is fed from a reservoir to the first (lowest) filtration step, where it partially moves in parallel to the membrane surface (tangential flow). The filtrate penetrates into the chamber

(reservoir) of the next (upper) disk and is partially filtered and partially recirculated; the process repeats at each next step with a membrane of smaller pore size. Therefore, both the particulate and dissolved components of each fraction remain in the aquatic media after the filtration run and thus are taken for subsequent analyses.

Matteson and Cheryan have provided detailed lists of commercially available membranes and described filtration units appropriate for analytical applications. The methods described below are based on utilization of 'inert' membranes, i.e., membranes that hardly absorb any of the solutes. Of course, any membrane has some adsorption ability, and so a certain conditioning should be provided to minimize the adsorption.

## Membrane Separation without Chemical Reagents

### Studies of Size Distribution Patterns for Trace Elements

Trace elements in natural waters may be present in different physicochemical forms varying in size, charge, and density. They may be associated with ligands ranging from simple ions to large molecules, or they may be absorbed onto or incorporated in organic colloids including humic and fulvic acids or inorganic particles, such as clay minerals and iron and manganese oxides. The binding of trace elements and radionuclides can enable the determination of transport, distribution, and biological uptake. Because of their impact on human and animal organisms, the distribution patterns of trace elements are important for environmental and biological studies. Methods using UF and MF are appropriate for the study of such patterns.

Figure 2 gives some characteristics of the size separation techniques that can be used to study the distribution of trace elements associated with various constituents of natural waters. It is obvious that the dimensions given in the figure are tentative as various factors influence the association/dissociation and aggregation/dispersion processes. However, preservation of real equilibria and labile species of elements, especially at concentrations of less than  $10^{-6}\text{ g l}^{-1}$ , prior to analysis is a much more serious problem encountered with methods that are not based on a direct physical separation. From this point of view, membrane filtration as well as some variants of field-flow fractionation (FFF) have advantages, although some uncertainties connected with equilibria shifts always exist.

**Figure 1** Flow diagram of a tangential-flow OMFD. M, membrane; F, fraction; R, retentate.

**Figure 2** Scheme for the speciation analysis of trace elements in river water using size fractionation techniques.

The pore size distribution is an essential characteristic of filters used to study size distribution patterns. As track-etched filters have a very narrow pore distribution (geometric standard deviation being less than  $\sim 1.1$ ), they are often used if fine solid particles are to be separated.

Track-etched polyethyleneterephthalate filters with pore sizes ranged from 8 to 0.025 μm and other types of membranes made of polysulfone, mixed cellulose ester, regenerated low binding cellulose, polycarbonate, and polyvinylidene fluoride, with pore sizes from 1.2 μm to 1 kDa, have been tested on OMFDs using soluble polymers and particles of known sizes, and the particle size distributions obtained have been checked using laser light scattering measurements. This technique has been subsequently applied to river and other natural waters of Germany, Russia, Switzerland, the Netherlands, and other European countries. Using such filtration systems five or six fractions of different particle sizes have been obtained, subsequently to be analyzed, e.g., using inductively coupled plasma (ICP)–atomic emission spectroscopy (AES) or mass spectrometry (MS), yielding the distribution patterns of the trace and major elements in waters. Suspensions of fine particles derived from polluted areas, e.g., from former uranium and tin mines located in central Germany, have also been analyzed after fractionation on an OMFD.

Informative distribution patterns can be obtained using only two or three filters having different pore sizes if the membrane filtration is combined with acidification of water fractions. Thus, an analytical scheme for determining the speciation of aluminum in natural waters has been described. The scheme is based on sizing by filtration of acidified and unacidified water sample portions through 0.1 and 0.4 μm

polycarbonate membrane filters. The following aluminum species have been detected using ultraviolet (UV)–visible spectrophotometric and atomic adsorption measurements after the separation: particulate, colloidal and soluble, large colloidal, fine colloidal and soluble, fine colloidal complexed, and labile (aluminum forms such as  $\text{Al}^{3+}$ ,  $\text{Al}(\text{OH})^{2+}$ , and  $\text{Al}(\text{OH})_2^+$  as well as total aluminum).

In the experiments with aluminum, the filtration was carried out under stirring. Acidification procedures and utilization of stirred filtration cells should be used with care because they may result in equilibria shifts.

Stirring can influence not only the equilibria between solutions and suspended colloidal forms but also the flux through UF membranes. Besides, the membranes of stirred UF cells clog relatively quickly in the presence of dissolved organic carbon, and the polarized membrane surface changes its retention behavior. In contrast, in the use of the tangential-flow technique, the surface of the membrane is continuously cleared of small particles and allows high flow rates. Hollow-fiber cartridges having a nominal molecular mass cutoff of  $10^6$ ,  $10^5$ ,  $10^4$ , or  $10^3 \text{ g mol}^{-1}$  have been used for successive filtration separations in natural water analysis.

Clogging and sorption effects have also been investigated for aluminum in natural waters. On the basis of the results obtained and studies of distribution patterns for aluminum, iron, and zinc as well as some radionuclides in natural waters, it has been shown that the main advantages with hollow-fibre fractionation are minimal clogging and sorption problems and a high filtering capacity in comparison to those of stirred-cell techniques.

Different methods for determination of the physicochemical forms of metals in waters have been

compared. If the fractionation is rapid, the risk of equilibria shifts during membrane filtration is less than for other fractionation techniques. The absence of gels or other separating materials that can adsorb trace elements and their species more readily than do polymer membranes enables minimization of sorption. The adsorption effects may also be reduced if preconditioning of the filtration unit with a sample aliquot is used. This can be easily done because MF, UF and FFF are faster than gel filtration, to say nothing of such a fractionation technique as sedimentation.

Different techniques are in use for analysis of the filtration fraction and concentrates. Most often multielement techniques such as ICP AES/MS and X-ray fluorescence (XRF) spectrometry are applied. Use of electrochemical methods and different techniques of atomic absorption spectrometry (AAS) is also possible.

It is obvious that the use of one membrane filtration method as a single separation technique cannot give comprehensive information on metal speciation in aqueous media. Combinations of UF with FFF, sedimentation, ion exchange, and liquid-liquid extraction are useful for the identification of the species of an element. However, membrane filtration itself is a rather powerful means if a number of membranes having different pore size are used for studying one sample.

### Membrane Filtration of Organic and Bioorganic Substances and Their Metal Complexes

Not only the molecular mass but also the conformation of organic molecules plays an important role in their retention by membranes; clearly the retention depends on the molecular shape and increases with the rigidity of the molecule. Similar results have been obtained for synthetic water-soluble polymers, proteins, and other biological macromolecules. It has been shown that the nature of the solvent, the nature and concentration of the electrolytes or complexable ions, and an increased concentration of polymer at the membrane surface due to concentration polarization may modify the conformation of the polymer and therefore its retention.

A special group of soluble organic macromolecules comprises humic substances (HSs; humic and fulvic acids), which are important transport agents for inorganic and organic contaminants, including radionuclides, in natural waters. According to current estimates, more than 50% of the dissolved organic carbon in natural waters consists of polyelectrolytes of the HS type. Therefore, characterization of HSs and their complexes is important for environmental

**Figure 3** Molecular-size classification of a sample of an HS (Venner Moor, Muensterland, Germany, 48 mg l<sup>-1</sup> DOC, pH 3.7) and its metal species in a selected bog water using an OMFD device. Fractions: 1, > 100 kDa; 2, 50–100 kDa; 3, 10–50 kDa; 4, 5–10 kDa; 5, 1–5 kDa; 6 < 1 kDa.

analytical chemistry. The possibility of characterizing HS in the colloidal and macromolecular size ranges after size fractionation on sequential-stage UF devices like OMFDs and on cascades of hollow-fiber modules has been shown. As an example, in **Figure 3** the size distribution patterns of an HS (Venner Moor, Muensterland, Germany) and some naturally occurring metal species in a typical bog water obtained on an OMFD, with UV spectrophotometric and AAS studies, are presented. Using UF, sized samples of the HS were chemically characterized using nuclear magnetic resonance spectroscopy, Fourier transform infrared spectroscopy, and other techniques. The studies have demonstrated that sufficient material can be obtained with UF with minimal alteration to the material. Inorganic analysis performed on the size fractions has shown that UF can also allow the binding capacity of the HS in each fraction to be measured.

UF has also been applied to the determination of stability constants for trace metal-HS complexes, equilibrium constants for the distribution of organic compounds between water and synthetic micelles, the binding of metal ions and small compounds to proteins and other macromolecules in biochemistry, etc. This type of application is essential to know precisely to what degree the complexing agent, the complexed species, and the free ions and molecules can pass through the membrane.

MF is used in bacteriological analysis of municipal waters and waste treatments. The identification of coliform bacteria in water indicates fecal contamination and the possible presence of pathogenic enteric organisms, which are responsible for causing

various diseases. The procedure commonly used in bacteriological assays in sanitation inspection consists of filtering the water sample, inhibiting or selectively growing the retained organisms, and counting these organisms. A 0.45  $\mu\text{m}$  pore diameter membrane is usually used in the water analysis. Microfilters are also applied in medical and clinical techniques in the detection of specific cells. Cytological examination with membrane filtration is performed on blood and urine.

The concentration of viruses in water is much lower than that of bacteria; therefore their preconcentration and separation from other suspended matter is important in virological analysis. Viruses may be enriched by UF by use of tangential-flow or hollow-fiber filtration units most suitable for preconcentration from large-volume water samples. Another possibility consists in adsorption of the viruses on the microfilter matrix followed by elution with diluents containing cell extracts, serum, or surfactants.

### Membrane Preseparations in Continuous-Flow Instruments

Physical separation of inorganic ions and other low-molecular analytes from the particulate and dissolved macromolecular fractions of the sample is useful in different flow instruments. Dialysis and UF membrane cells are amongst practical systems for flow injection analysis (FIA), which serve to exclude any unwanted sample material so that only the analyte reaches the reaction or sensing zone. Solid particles and large interfering molecules can be separated using membranes from the smaller species of analytical interest. Such cells can also be used in the continuous-flow, stopped-flow, and sequential injection modes of flow analysis. The membrane preseparation units are very attractive because they are simple, repeatable, require little or no pretreatment of sample, and show no interferences from sample color and turbidity; in most cases no reaction in the membrane interface is involved.

Membrane filtration can be used in sample preparation for liquid chromatography, e.g., in the ion-chromatographic determination of various inorganic anions and cations in water samples. Tubular membrane interfaces have been used for sample introduction in capillary zone electrophoresis to separate the low-molecular mass organic constituents of blood plasma.

Reagent delivery cells with a track-etched polycarbonate membrane filter (pore size 0.1–0.01  $\mu\text{m}$ ) for online dilution of concentrated salt solutions have been described. By using a reagent delivery cell, the

ageing of solutions is avoided, leading to long-term stability, and pipetting errors and waste are minimized. Such cells are useful for calibration purposes, required in many areas of analytical chemistry.

## Membrane Separation Using Chemical Reagents

### Collection of Trace Elements on a Membrane Filter

A chemical reagent added to the aqueous sample, added to the recipient solution, or built in the membrane can improve the separation or increase the concentration efficiency. If the reagent is built in, the membrane is called adsorptive or chemically active. If an 'inert' solid membrane is used, an inorganic reagent or organic monomeric or polymeric agent is added to the sample to obtain insoluble compounds of analytes. Different cellulose-based membranes (pore diameter 0.45–3.0  $\mu\text{m}$ ) have been utilized for the purpose.

A sensitive spectrophotometric method for the determination of phosphorus has been proposed. The ion associate of molybdophosphate with Malachite Green is filtered through a membrane filter (cellulose nitrate; pore size 1.0  $\mu\text{m}$ , diameter 9 mm) and then dissolved together with the membrane filter in methyl Cellosolve and the absorbance measured using a FIA system equipped with an autosampler. For filtration of the ion associate, a special filtration apparatus has been designed. Other procedures have been developed for determination of phosphate, arsenate, arsenite, and silicate as heteropoly species collected on the filter and dissolved, together with the filter, in dimethyl formamide or another organic solvent. The analytes can also be washed out from the membrane surface for subsequent analysis of the liquid concentrate, or they can be directly analyzed on the filter using XRF. Various metal ions have been determined after preconcentration on a membrane in the form of metal chelates.

Removal of the analyte-containing precipitate using a thin membrane filter is similar to conventional filtration using a filter paper. However, there is a difference: the precipitate does not penetrate the membrane filter material, thus facilitating its quantitative removal from the membrane surface for subsequent analysis.

### Liquid-Phase Polymer-Based Retention

Soluble complexing polymers are being used in selective membrane separations of inorganic ions in a homogeneous aqueous phase. Such polymeric reagents form soluble polymer complexes that are

separated from low-molecular mass compounds through membrane filtration processes. Thus, uncomplexed inorganic ions can be removed with the filtrate, whereas the water-soluble polymer complexes are retained. To separate and preconcentrate metal ions, their solution, to which a polymer is added, can be passed from a reservoir into the filtration unit. Another procedure of absolute preconcentration has been recommended in which the polymer reagent is added directly to the cell and then a large volume sample is passed through a solution of a relatively high and constant polymer concentration.

However, interfering components of the test solution partly remain in the cell after the filtration run, even when they do not interact with the reagent. This can cause difficulties, e.g., in trace analysis of highly mineralized waters. Therefore, a combined procedure is of interest: a sample with a large volume is passed through a much smaller volume of polymer solution in the cell and then washed with pure water to remove remaining amounts of constituents not complexed by the polymer. Thus, both absolute and relative preconcentration are achieved.

Conventional stirred filtration cells or a specially designed radial-flow cell equipped with a pump can be used. Membranes made of polysulfone, polyamide, cellulose, etc. are suitable. The essential parameters are the molecular mass exclusion rate in wide pH ranges (1–10) and an appropriate permeate flow rate ( $1\text{--}10\text{ ml min}^{-1}$ ), retentate volume (2–10 ml), and gas pressure (300 kPa is a suitable pressure in most cases). A nominal exclusion rate of  $10\text{ kg mol}^{-1}$  has been shown to be convenient for polymers having a molecular mass between 30 and  $50\text{ kg mol}^{-1}$ . A polymer concentration of 1–4% (w/v) in the cell solution is most appropriate for both retention of elements and their subsequent determination in the retentate.

Poly(ethylene imine) (PEI), poly(acrylic acid), poly(1-vinyl-2-pyrrolidone), and other widely used polymers have been used for preconcentration and separation of various elements. Reagents with typical acidic chelating groups have also been used: 8-quinolinol and iminodiacetic groupings, neutral thiourea groups and trimethylammonium-based anion-exchange groups. Introduction of strong chelating groups into the basic polymer backbone results in more effective retention of metal ions.

The technique described above is called liquid-phase polymer-based retention (LPR) or polyelectrolyte-enhanced UF. Another variant of the separation

and preconcentration of low-molecular mass solutes in an UF cell, called micellar-enhanced ultrafiltration, is based on solute retention in the micellar phase obtained from surfactants. Procedures have been developed for the preconcentration of Al as a complex with lumogallion, of Co and Ni with organophosphorus reagents in the presence of a cationic or nonionic surfactant, and of various heavy metals with PEI in the presence of inorganic colloids formed by iron(III) hydroxide.

Preconcentration of elements using the LPR method can be combined with different determination methods, e.g., with AAS, ICP AES or MS, stripping voltammetry, and other techniques applicable to the analysis of aqueous solutions. The final solution (concentrate) obtained after the separation is an aqueous solution of 1–4% polymer that does not interfere significantly with the determination methods mentioned above.

### Introduction

The analysis of complex samples frequently necessitates pretreatment of the sample to separate the analyte from the matrix. In some cases analyte separation also results in preconcentration. Conventional analytical separation involves physicochemical processes, such as precipitation, adsorption, ion exchange, and extraction.

Extraction, in its various forms, is one of the most frequently used separation processes in the analytical practice. In this process the analyte is transferred from the sample, usually a liquid, to another immiscible phase, which is usually a condensed phase. If the condensed phase is a liquid the extraction technique is called liquid-liquid or solvent extraction. In the case of a solid condensed phase, the corresponding extraction technique can be either solid-phase extraction (SPE) or solid-phase microextraction (SPME).

In liquid-liquid extraction (LLE), the analyte is partitioned between two immiscible liquid phases, which are usually an aqueous sample and an organic solvent. The possibility of dissolving organic compounds in the solvent capable of chemically interacting with the analyte (e.g., forming complexes or ion pairs) can improve substantially the selectivity and efficiency of the extraction process on the one hand and widen the range of analytes (e.g., from ionic inorganic species to nonpolar organic compounds), which can be separated by LLE, on the other. The main disadvantages of LLE are associated with the use of relatively large volumes of organic solvents, which are often expensive and toxic and may form stable emulsions with the aqueous phase. The low sample to solvent volume ratio does not allow high enrichment factors. These drawbacks of LLE can be overcome to a considerable extent by SPE, SPME, and solvent microextraction (SME), known also as liquid-phase microextraction. When the analytical procedure involves further separation and detection in the aqueous phase (e.g., reversed-phase high-performance liquid chromatography) following the LLE step, an additional back-extraction step from the organic phase into a new aqueous phase must be introduced, which complicates the separation process.

In SPE, a solid sorbent material (e.g., resin or alkyl bonded silica) packed into a cartridge or imbedded

into a polytetrafluoroethylene (PTFE) or glass fiber disk, replaces the organic solvent used in LLE. Separation in SPME is based on absorption or adsorption of the analyte into the coating of a fused silica fiber, which may be a thin nonvolatile liquid film (e.g., polydimethylsiloxane) or a porous solid (e.g., C18-bonded silica). The relatively small number of suitable sorbents reduces the applicability of both SPE and SPME to the separation of mainly organic analytes of low polarity and limits the selectivity of these techniques compared to that offered by LLE. Analytes are usually thermally desorbed in SPME while analyte adsorption in SPE is followed by elution with a relatively small amount of an organic solvent.

In SME, a single microdrop of the organic phase (e.g., n-octane, toluene), which may contain an internal standard, is usually suspended in the sample solution on the tip of a microsyringe needle. After a predetermined extraction time the drop is retracted back into the microsyringe to be injected later into a gas chromatograph. Repeated suspending and retracting of the organic microdrop in the microsyringe can induce convective mass transfer within both the microdrop and the sample solution adjacent to it, resulting in high enrichment factors. Alternatively, the concentration of the extracted analyte can be determined spectrophotometrically directly in the microdrop if it forms a colored compound. SME has been successfully applied to headspace analysis. Similarly to LLE, SME offers higher selectivity compared to SPE and SPME, but it is not readily adaptable to analytical separations where back-extraction is required.

Membrane separation involving liquid membranes is an attractive alternative to the extraction techniques outlined above. Like SPE and SPME, separation based on liquid membranes requires small amounts of organic solvents, if any, while at the same time it offers the high selectivity, flexibility, and enrichment factors of LLE and SME. Liquid membranes are suitable for online analytical separation, since the extraction and back-extraction are integrated into a single step, unlike the sequential arrangement of these processes when other extraction techniques are used.

### Membranes and Related Processes Used in Analytical Separation

In most membrane separation processes, the membrane separates two miscible or immiscible fluid

phases, each one of which can be either static or mobile. Most frequently the two fluids are liquids, one of which is the liquid sample (often referred to as the feed or donor solution) while the other liquid is usually referred to as the receiver, strip, or acceptor solution. The membrane prevents mixing and, very often, direct contact between the two solutions. The latter function of the separation membrane is particularly important when the feed and receiver solutions are miscible fluids or when analyte preconcentration is also required.

The membranes used in analytical separation processes are usually single- or dual-phase membranes.

### Single-Phase Membranes

Depending on its aggregate state a single-phase (SP) membrane can be solid or liquid. Typical examples of solid SP separation membranes are nonporous polymer membranes made of silicone rubber. These membranes have been used successfully in membrane introduction mass spectrometry or gas chromatography where a receiver gaseous phase is used. Mechanical stability and relatively long lifetime compared to other types of separation membranes are among the main advantages of nonporous polymer membranes. However, these membranes are hydrophobic in character and thus are limited to the separation of mainly nonpolar analytes. Another drawback of nonporous polymer membranes is their low permeability, resulting in slow mass transfer between the feed and receiver solutions.

Emulsion and bulk liquid membranes, which will be outlined later in this article, are typical liquid SP membranes.

### Dual-Phase Membranes

The dual-phase (DP) membrane used in analytical separation usually consists of a polymer, or in some cases a ceramic solid-phase support impregnated with a fluid (i.e., gaseous or liquid phase). If the fluid is air the DP membrane is known as a gas-diffusion membrane. DP membranes incorporating a liquid phase can be considered in a broader sense as liquid membranes. The liquid phase in a liquid DP membrane can be identical to the feed and/or receiver solution (e.g., dialysis membranes, membrane-assisted LLE (MALLE)) or it can form a third immiscible liquid phase in the membrane separation system (e.g., supported and polymer liquid membranes). Membranes incorporating a liquid phase immiscible with the feed and receiver solutions are usually referred to as liquid membranes. This narrower definition of liquid membranes, currently accepted in the literature, will be used in subsequent discussions. The

membranes covered by this definition, which can be either SP or DP membranes, will be outlined in more detail separately.

**Gas-diffusion membranes** Hydrophobic porous polymer membranes with air filling the membrane pores have been used successfully in the online separation of volatile and semivolatile analytes between two miscible liquid streams in flow injection analysis (FIA) systems. The corresponding technique is frequently referred to as gas-diffusion FIA. The mass transfer of an analyte across a gas-diffusion membrane is controlled by the membrane pore size and the solubility of the analyte in the feed and receiver solutions. The latter can be manipulated by appropriately modifying the chemical composition of the two solutions. In this way it is possible to enhance both the evaporation of the analyte from the feed solution into the membrane pores and its subsequent absorption into the receiver solution.

**Membranes for dialysis and membrane-assisted liquid-liquid extraction** Depending on the hydrophobicity of a porous polymer membrane and the solutions in contact with it, the membrane pores can be filled with the feed solution, the receiver solution, or a mixture of both solutions. If both solutions are miscible (e.g., aqueous) the separation of the analyte is based on dialysis, while if they are immiscible the separation process is often referred to as MALLE.

Dialysis describes a separation process usually involving two aqueous phases (i.e., feed and receiver solutions) divided by a hydrophilic (e.g., cellulose acetate) porous membrane. The membrane pores are filled with water and solutes from both the feed and the receiver solutions. Typically, dialysis is utilized for the determination of low molecular weight analytes in samples containing macromolecular species like proteins (e.g., chloride in milk). The average pore size determines the molecular mass range within which chemical species can cross the membrane. The driving force in dialysis is the analyte concentration gradient across the membrane (i.e., passive dialysis). If an external electric field is applied electrodialysis takes place. Both dialysis and electrodialysis have been frequently used as online separation techniques in FIA systems. When the analytes are charged chemical species, they can be separated from the sample matrix and preconcentrated in an acceptor solution by means of Donnan dialysis. In this process, an appropriately selected ion-exchange membrane (e.g., Nafion) separates the sample from an acceptor solution of a smaller volume and higher ionic strength. Ions of appropriate charge from the receiver solution are transported into the sample

solution as a result of the existing ionic strength gradient while co-ions from the sample solution including the analyte ions diffuse in the opposite direction in order to maintain electroneutrality. Electrodialysis and Donnan dialysis, unlike passive dialysis, allow preconcentration of the analyte as well.

In MALLE a hydrophobic or hydrophilic porous polymer membrane separates two immiscible phases, usually an organic receiver phase and an aqueous feed (sample) phase. If the membrane is hydrophobic, its pores are filled with the organic receiver phase and the actual analyte partitioning takes place at the membrane/feed solution interface. The analyte then diffuses across the membrane into the bulk of the organic receiver solution. Unlike LLE, MALLE does not require mechanical mixing of the two phases followed by phase separation, as a result of which the extraction process can be miniaturized and conducted online. However, similarly to LLE, analyte separation and preconcentration in MALLE is governed by the corresponding aqueous/organic partition coefficient. MALLE has been implemented in FIA as an attractive alternative to the technically more complex segmented LLE flow injection approach, involving phase segmentation, extraction, and phase separation prior to detection in the organic phase. Another recent analytical application of MALLE, based on SME, is the so-called extracting syringe or hollow fiber protected liquid-phase microextraction where a hollow fiber connected to the stainless steel needle of a microsyringe is filled with a suitable organic solvent (e.g., cyclopentane) and exposed to a flowing or mechanically stirred aqueous sample. After extraction, the solvent in the fiber is retracted back into the syringe and subsequently injected into a gas chromatograph.

## Liquid Membranes

By definition the membrane liquid phase of a liquid membrane must be immiscible with the solutions in contact with it. This allows the chemical composition of all three liquid phases (including the membrane liquid phase) to be altered independently of one another. For this reason liquid membranes offer a higher degree of control over the membrane separation process compared to other types of separation membranes.

### Classification

The liquid membranes most often employed in analytical and industrial separation are: supported liquid membranes, polymer liquid membranes, emulsion liquid membranes, and bulk liquid membranes.

**Supported liquid (SL) membranes** The SL membrane is the most frequently used type of liquid membrane in analytical separation. An SL membrane can be constructed by impregnating the pores of a porous hydrophobic membrane (e.g., PTFE; poly(vinylidene fluoride) (PVDF); polypropylene) with a suitable organic liquid (**Figure 1A**). The porous solid membrane phase acts as a support for the liquid phase retained in the membrane pores by capillary forces.

The main disadvantage of the SL membrane is the slow leaching of the membrane liquid phase into the receiver and feed solutions, thus reducing its lifetime. Attempts have been made to slow down the loss of the membrane liquid phase by converting it to a polymer gel. The corresponding SL membrane is known as gelled SL membrane.

The liquid membrane in a recently introduced solvent microextraction/back-extraction (SME/BE) technique, where the organic phase separating the feed and receiver aqueous phases is located within a PTFE ring (i.d. 6.4 mm), can be viewed as an SL membrane with a single macropore. Very high enrichment factors can be achieved if the aqueous receiver solution is suspended as a microdrop from the tip of a microsyringe needle in the organic membrane. SME/BE allows the use of fresh liquid membrane for each extraction, thus eliminating memory effects and long-term stability problems.

**Polymer liquid (PL) membranes** The PL membrane is a relatively new type of self-supporting liquid membrane, which resembles the SL membrane. Similarly to the SL membrane, the PL membrane incorporates a liquid extractant in the membrane polymeric structure. In some cases the incorporation of additional organic compounds (plasticizers) is required to achieve homogeneity and sufficient flexibility of the membrane.

PL membranes are usually cast from a homogeneous solution of the dissolved solid polymer material (e.g., poly(vinyl chloride)), the liquid extractant (e.g., Aliquat 336 chloride; DEHPA) and a plasticizer (e.g., dioctylphthalate; n-decanol) in a suitable solvent (e.g., tetrahydrofuran) by the slow evaporation of the solvent. By increasing the concentration of the extractant the permeability of the PL membrane increases while at the same time its mechanical stability deteriorates. For example, the optimal concentration range for Aliquat 336 chloride in a polyvinyl chloride based PL membrane is between 40 and 50%.

The structures of PL membranes are currently being elucidated. Surface analysis results have suggested the presence of networks of nano-sized channels filled with the liquid extractant and diluent. The small size of these channels explains the facts that PL

**Figure 1** Schematic of: (A) SL membrane sandwiched between two mechanically stirred extraction cells; (B) EL membrane; and (C) BL membrane.

membranes are homogeneous at macrolevel, and that the rate of loss of the liquid membrane phase components is small compared to that in SL membranes. The latter fact is responsible for the longer lifetime of PL membranes.

**Emulsion liquid (EL) membranes** A typical EL membrane consists of emulsion globules (extracting emulsion) of the receiver solution and the organic membrane liquid phase. The emulsion globules are stabilized by a surfactant (e.g., sorbitan monooleate) and are dispersed in the feed aqueous solution (Figure 1B). The resulting double emulsion is characterized by a large interfacial surface area between the emulsion globules and the feed solution on the one hand, and within the emulsion globules, between the receiver phase, and the organic liquid membrane phase on the other. This configuration allows fast mass transfer between the feed and receiver phases. By appropriate selection of the composition of the extracting emulsion (i.e., electrolyte composition of the receiver phase, concentration of emulsifier, adsorption of solid particles on the interface of the emulsion globules, formation of nanodispersion droplets by using microemulsifiers) high stability to coalescence and sedimentation can be achieved. These properties of EL membranes are crucial in avoiding mixing between the feed and receiver solutions during the separation process.

After equilibrium in the system has been attained, the aqueous feed phase is separated from the receiver phase emulsion globules, which are further demulsified (e.g., by adding *n*-butanol) to form an organic liquid membrane layer and an aqueous receiver layer. After the separation of these two liquid layers the aqueous receiver solution is analyzed.

EL membranes allow high enrichment factors due to the large ratio of feed solution to receiver solution volume. The presence of emulsifiers and the relatively larger volume of the membrane liquid phase in EL membranes compared to that in SL membranes allow the organic diluents and carriers in EL membranes to be less hydrophobic than those normally used in SL membranes. This extends the range of membrane liquid phases that can be used in EL membrane extraction.

The currently existing difficulties in handling EL membranes, associated mainly with the formation and breakdown of the emulsion itself, have prevented the widespread use of this type of liquid membrane in the analytical practice despite the advantages outlined above.

**Bulk liquid (BL) membranes** A BL membrane consists of a layer of membrane liquid phase in contact with both the aqueous feed and receiver solutions, located in separate compartments. Depending on its density, the membrane liquid phase can be placed either above or below the two aqueous phases (Figure 1C). Mechanical stirring of the feed and receiver solutions, and in some cases of the membrane

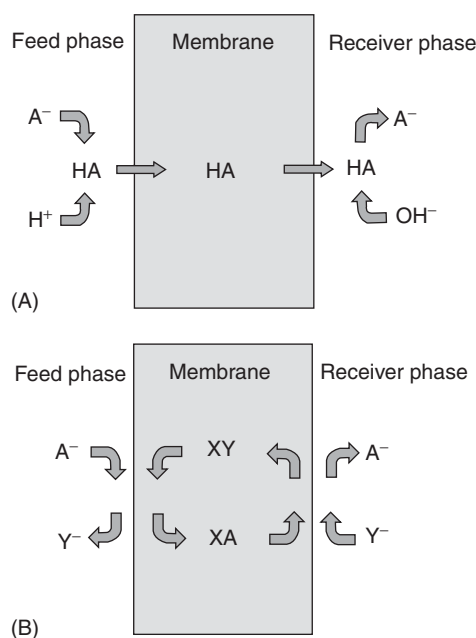

liquid phase, is required to enhance the mass transfer processes in the three-phase system. BL membranes are not suitable for routine analyte separation because of the complex manual operations involved in conducting this analytical procedure. The main analytical interest in this type of liquid membrane is based on the fact that they use small quantities of carrier and diluent compared to traditional LLE, and therefore are suitable for screening carrier properties.

### Liquid Membrane Separation

**Mechanism** Membrane separation involves the following membrane-based processes: (1) transfer of the analyte from the feed solution to the membrane liquid phase as a result of partitioning or chemical reaction, producing a lipophilic complex or ion pair; (2) membrane transport of the analyte or its complex by Fickian diffusion driven by the corresponding concentration gradient across the membrane; and (3) transfer of the analyte from the membrane liquid phase to the aqueous receiver solution. The membrane concentration gradient can be maintained at its maximum by minimizing the analyte concentration in the receiver solution at the corresponding membrane/solution interface. This result can be achieved by (1) converting the analyte entering the receiver solution into another chemical species, usually using a suitable protolytic or complexation reaction; (2) inducing convective mass transfer (e.g., mechanical stirring or flow); or (3) combining approaches (1) and (2). Approach (2) can also be used to enhance the mass transfer of the analyte from the bulk of the feed solution to the corresponding membrane/solution interface.

Depending on the chemical composition of the membrane liquid phase, the mass transfer of the analyte from the feed to the receiver solution can be either passive or facilitated.

**Passive mass transfer** In the case of passive mass transfer, the membrane liquid phase consists of an organic solvent or a mixture of organic solvents. The transfer of the analyte across both membrane/solution interfaces is governed by its partition coefficient. **Figure 2A** illustrates schematically the passive transport of an organic acid across a liquid membrane involving suitable protolytic reactions in both the feed and receiver solutions. If the volume of the receiver solution is smaller than the volume of the feed solution the analyte of interest can be concentrated as well. The mechanism of passive liquid membrane separation is analogous to that involved in separation based on solid SP and gas-diffusion membranes. However, unlike these membranes, liquid membranes

**Figure 2** Schematic representation of: (A) passive membrane mass transfer; and (B) facilitated membrane mass transfer ( $A^-$  is the analyte anion and  $X^+$  is a cationic carrier).

exhibit a higher degree of flexibility due to the ease with which the membrane liquid phase composition can be modified to meet the specific requirements of the analyte of interest (e.g., polarity).

Organic solvents used in liquid membranes for both passive and facilitated transfer can be either nonpolar aliphatic or aromatic hydrocarbons such as toluene and kerosene, or polar organic compounds such as dihexylether. The polarity of the membrane liquid phase can be modified readily by the addition of small amounts of hydrophobic polar organic solvents (e.g., trioctyl phosphine oxide, dodecanol). Liquid membranes are generally more permeable than solid SP membranes thus allowing faster separation. They are also suitable for the separation of both volatile and nonvolatile analytes.

**Facilitated mass transfer** Similarly to LLE, the selectivity and efficiency of the liquid membrane separation process can be considerably improved if a suitable extractant with a high selectivity for the analyte of interest is used. This extractant, often referred to as the carrier, facilitates the mass transfer of the analyte between the feed and receiver solutions. The liquid membrane phase in this case usually consists of a suitable liquid extractant or an extractant dissolved in an organic solvent (diluent). The extractant facilitates the transport of the analyte from the feed phase to the liquid membrane phase by chemically interacting with it. This interaction leads to the selective extraction of the analyte into the

membrane liquid phase as a complex or an ion pair. The analyte is released into the receiver solution at the membrane/receiver solution interface as a result of another ion exchange reaction, and the freed carrier diffuses back to the membrane/feed solution interface. A typical liquid membrane cationic carrier is the positively charged quaternary ammonium ion Aliquat 336 (tricaprylmethylammonium cation). Frequently used anionic carriers are the negatively charged lipophilic conjugated bases of organic acids (e.g., di-2-ethylhexyl phosphoric acid, DEHPA). Both cationic and anionic carriers form neutral ion pairs with the oppositely charged ionic analyte. Metal complexes of macrocyclic ligands with hydrophobic functional groups such as sodium 1,10-didecyl-1,10-diaza-18-crown-6 complex (Na-22DD) have been used successfully as carriers in the membrane separation and preconcentration of metal ions. Ligand substitution reactions take place at both membrane/solution interfaces in these cases. Figure 2B shows schematically a typical mechanism of facilitated liquid membrane separation process involving a cationic carrier ( $X^+$ ).

## Analytical Applications of Liquid Membranes

The analytical interest in BL and EL membranes is based mainly on their use as a convenient research

tool in screening carriers and determining the optimal composition of SL membranes. PL membranes, as a relatively new class of liquid membranes, have shown promising results in metal separation and preconcentration. Though there are numerous environmental and clinical applications of SL membranes, these liquid membranes have been used in a few instances only in food and beverage analyses (e.g., biogenic amines in wine, vanilla in chocolate and sugar, nicotine in Swedish snuff, and caffeine in coffee).

### Environmental Applications of SL Membranes

Most of these applications are in the area of water analysis for the determination of various pesticides, carboxylic and amino acids, aromatic compounds, surfactants, aniline derivatives, and metal ions. There are a few applications of SL membranes in soil and air analysis of carboxylic acids (Table 1).

### Clinical Applications of SL Membranes

Most of these applications are focused on the determination of heavy metals, drugs, and other biologically active compounds in blood plasma, breast milk, and urine (Table 2).

### Liquid Membrane Separation Units

Depending on the geometry of the solid polymer support, SL membranes can be produced in the form

**Table 1** Analytes determined in environmental samples after SLM separation

Amino acids	Tryptophan, phenylalanine, tyrosine
Aniline and its derivatives	Aniline, chloroanilines, methylanilines, chloromethylanilines
Aromatic compounds	Nitrophenols, chlorinated phenols, phenolic acids (benzoic, <i>p</i> -hydroxybenzoic, vanillic, caffeic, <i>p</i> -coumaric, ferulic, salicylic, phenazine-1-carboxylic), aromatic anionic surfactants (alkylbenzenesulfonates)
Carboxylic acids	Monocarboxylic acids (formic, acetic, propionic, butyric, iso-butyric, valeric, iso-valeric), dicarboxylic acids (glutaric, dimethylglutaric, adipic)
Metal ions	Cu(II), Pb(II), Cd(II), Zn(II), Ni(II), Al(III), Cr(III), Cr(VI)
Pesticides	Phenoxy acids (2,4-dichlorophenoxy acetic acid, MCPA, and 2,4,5-trichlorophenoxy acetic acid) and similar acid herbicides (benzaton, dicamba, dichlorprop, and mecoprop); sulfonurea herbicides (chlorsulfuron, metsulfuron methyl, tribenuron methyl, and thifensulfuron methyl); triazine herbicides (methoxy- <i>s</i> -triazines, chloro- <i>s</i> -triazines, alkylthio- <i>s</i> -triazines); phenylurea herbicides (fenuron, monolinuron, and diuron), metabolites of the fungicide thiophanate-methyl (carbenazim and 2-aminobenzimidazole)

**Table 2** Analytes determined in biological fluids after SLM separation

Biologically active compounds	Aliphatic and aromatic amines (methyl-, ethyl-, propyl-, and octyl-amines, piperidine, 1-ethylpiperidine, <i>N</i> -methylmorpholine, cyclohexylamine, <i>N,N</i> -dimethylcyclohexylamine, pyrrole, pyrrolidine, pyridine, aniline); phenols (phenol, <i>p</i> -cresol, 4-chlorophenol)
Drugs	Amperozide, amphetamine, methamphetamine, bambuterol, antidepressants (paroxetine, fluvoxamine, mianserin, and citalopram), anabolic steroids (glucuronides); promethazine, methadone, haloperidol, ibuprofen, naproxen, ketoprofen, propofol, ropivacaine
Metal ions	Pb(II), Mn(II)

of flat sheets or hollow tubes. So far PL membranes have been produced only as flat sheets.

### Flat Sheet Membrane Units

Flat sheet membrane units incorporating SL membranes have been used for both offline and online analytical separation.

Offline separation can be conducted in a system consisting of two mechanically stirred extraction cells (Figure 1A) attached on both sides of the flat liquid membrane. One of the cells is filled with the sample solution while the other is filled with the receiver solution. Similar extraction systems have also been used in determining the permeability of SL and PL membranes and in studying the extraction mechanism and kinetics involved in membrane separation processes.

A typical flow-through membrane unit allowing online separation usually consists of two halves made of a chemically inert polymer material (e.g., PTFE, PVDF), each furnished with a shallow groove. The two halves are separated by a flat liquid membrane. The groove connected to the feed (donor) solution stream is called the donor chamber, while the other groove is called the acceptor chamber (Figure 3A). The grooves can be linear, meander shaped, or arranged as an Archimedes' spiral (Figure 3B). Typically the groove width and depth can vary in the range from 1 to 3 mm and from 0.1 to 0.5 mm, respectively. Though the two grooves must face each other, they can differ in depth. In most cases, however, they have identical dimensions.

The donor and acceptor solutions usually flow concurrently through the membrane separation unit (continuous mode). Higher efficiency can be achieved by decreasing the acceptor solution flow rate with respect to the donor solution flow rate, or by stopping the acceptor solution for a predetermined period of time to trap the analyte into the stagnant acceptor solution located in the acceptor chamber (stopped-flow mode). The acceptor solution can be flown through a suitable flow-through detector for measuring the analyte concentration or it can be analyzed offline. In many sample clean-up applications the acceptor solution is introduced into a high-performance liquid chromatograph or a gas chromatograph for further separation.

### Tubular Membrane Separation Units

A typical flow-through tubular membrane separation unit frequently consists of two concentric tubes (Figure 3C) and usually operates in a stopped-flow mode. The acceptor solution is located in the inner

**Figure 3** Schematic of: (A) flow-through membrane separation unit for flat sheet membranes; (B) top view of one of the unit's halves with linear, meander, and Archimedes' spiral groove; and (C) tubular flow-through membrane separation unit.

tube, which in most cases is a single porous hollow fiber impregnated with a suitable organic solvent (e.g., 1-octanol, 6-undecanone). The sample (donor) solution flows through the outer tube made of polymer material (e.g., Kel-F) or glass. It is also possible to immerse the hollow fiber SL membrane in a vial containing sample solution, which may be mechanically stirred. A tubular membrane separation unit incorporating a hollow fiber SL membrane connected to the needle of a microsyringe can be operated as an extracting syringe.

Hollow fiber SL membranes allow faster analyte separation and higher enrichment factors compared to flat sheet membranes because of their high surface area to solvent volume ratios. Solvent volumes of the order of several microliters can be employed, which allows the coupling of hollow fiber SL membrane separation to other low sample capacity separation techniques (e.g., packed capillary liquid chromatography, capillary electrophoresis).

### Introduction

Pervaporation is a nonchromatographic membrane-based separation technique extensively used in industry. The separation is not based on relative volatilities, as in the case of distillation or evaporation, but rather on the relative rates of permeation through the polymeric membrane. It is based on the diffusion of volatile substances from a donor stream, through a porous hydrophobic membrane, to an acceptor stream caused by a temperature or pressure gradient.

Analytical pervaporation can be defined as a combination of continuous evaporation and gas diffusion through a gas permeable membrane. Both processes

take place in a single step and in the same unit. The volatile analyte (or its volatile reaction product) present in a heated donor phase evaporates through a porous membrane; then, an acceptor stream collects it and, finally, it is conveniently detected. Between the sample in the donor chamber and the membrane there is an air gap, which avoids the clogging of the membrane pores when analyzing dirty samples, and permits the presence in the donor chamber of species such as high molecular weight components, acids, bases, organic solvents, which would have deteriorated the membrane if they got in contact with it. This fact is the most outstanding feature of analytical pervaporation versus its industrial counterpart and other membrane-based nonchromatographic techniques such as dialysis and gas diffusion.

Analytical pervaporation can be carried out in a continuous way if the sample reaches the pervaporator by means of a continuous manifold, or in a discrete mode if the sample is introduced by injection,

tube, which in most cases is a single porous hollow fiber impregnated with a suitable organic solvent (e.g., 1-octanol, 6-undecanone). The sample (donor) solution flows through the outer tube made of polymer material (e.g., Kel-F) or glass. It is also possible to immerse the hollow fiber SL membrane in a vial containing sample solution, which may be mechanically stirred. A tubular membrane separation unit incorporating a hollow fiber SL membrane connected to the needle of a microsyringe can be operated as an extracting syringe.

Hollow fiber SL membranes allow faster analyte separation and higher enrichment factors compared to flat sheet membranes because of their high surface area to solvent volume ratios. Solvent volumes of the order of several microliters can be employed, which allows the coupling of hollow fiber SL membrane separation to other low sample capacity separation techniques (e.g., packed capillary liquid chromatography, capillary electrophoresis).

### Introduction

Pervaporation is a nonchromatographic membrane-based separation technique extensively used in industry. The separation is not based on relative volatilities, as in the case of distillation or evaporation, but rather on the relative rates of permeation through the polymeric membrane. It is based on the diffusion of volatile substances from a donor stream, through a porous hydrophobic membrane, to an acceptor stream caused by a temperature or pressure gradient.

Analytical pervaporation can be defined as a combination of continuous evaporation and gas diffusion through a gas permeable membrane. Both processes

take place in a single step and in the same unit. The volatile analyte (or its volatile reaction product) present in a heated donor phase evaporates through a porous membrane; then, an acceptor stream collects it and, finally, it is conveniently detected. Between the sample in the donor chamber and the membrane there is an air gap, which avoids the clogging of the membrane pores when analyzing dirty samples, and permits the presence in the donor chamber of species such as high molecular weight components, acids, bases, organic solvents, which would have deteriorated the membrane if they got in contact with it. This fact is the most outstanding feature of analytical pervaporation versus its industrial counterpart and other membrane-based nonchromatographic techniques such as dialysis and gas diffusion.

Analytical pervaporation can be carried out in a continuous way if the sample reaches the pervaporator by means of a continuous manifold, or in a discrete mode if the sample is introduced by injection,

either with the aid of a valve or a syringe. The first option allows simplification and miniaturization of preliminary operations, which clearly improves analytical quality and productivity.

## The Analytical Pervaporator and Auxiliary Units

### The Pervaporator Body

A pervaporation module designed for analytical purposes, **Figure 1**, consists of the following parts:

1. An upper acceptor chamber fitted with inlet and outlet orifices through which the acceptor stream (liquid or gas) is circulated, and in which the pervaporated analyte (or its volatile reaction product) is collected.
2. A membrane support of small thickness.
3. Spacers of varying thickness, if necessary, to increase the volume of the corresponding chambers.
4. A donor chamber (lower part of the unit) where the feed stream is circulated.

The conventional pervaporation unit is usually made of methacrylate, which is a transparent material that allows continuous checking of the performance of the unit. The different parts of the pervaporator are aligned by the insertion of metallic

rods in the drilled orifices and a closer contact is achieved by screwing them together with four screws between two metallic supports. With the aim of integrate pervaporation with detection, some changes must be done on the acceptor chamber in order to place a probe sensor.

### Membranes

The separation of various components from a liquid mixture is not only determined by differences in their vapor pressure, but also by their permeation rate through the membrane. The mechanism of transport through the membrane can be described as comprising three consecutive steps:

- sorption of the volatile components at the membrane surface;
- diffusion of the sorbed components through the polymer matrix; and
- evaporation from the polymer into the vapor phase on the permeate side of the membrane.

The efficiency of the pervaporation process is controlled mainly by the intrinsic properties of the polymers used for membrane preparation. It has been demonstrated that permeability in glassy polymers (cellulose) is lower than that in rubbery polymers (polydimethylsiloxane). Moreover, as the contribution of the solubility to the permeability dominates in nonglassy polymers, the permeability increases with increasing molecular mass of permeants.

Selectivity depends on the molecular dimensions of the permeating species. Thus, the hydrophobic membranes for analytical pervaporation are usually made of polytetrafluoroethylene and they are similar to those used in processes like ultrafiltration and gas diffusion.

### The Auxiliary Manifold

The simplest way of giving pervaporation the character of a continuous separation technique is its coupling to a dynamic manifold for assistance of both donor and acceptor chambers. In the first instance, when the samples are liquid, the coupling with the manifold (usually a flow-injection (FI) arrangement) is mandatory for driving the sample either by injection or aspiration to the donor chamber. In addition, (bio)chemical and/or physical steps, namely, reactions that convert the analyte into the most appropriate form for being evaporated, physical dispersion, etc., can also be developed in the manifold prior to the arrival of the sample to the donor chamber; meanwhile, a detector can be located in postpervaporator position in order to monitor nonvolatile species. When the sample is a solid, the

**Figure 1** Parts of a pervaporation module: (A) acceptor chamber; (B) membrane support; (C) spacer; (D) donor chamber; (E) aluminum supports; (F) and (G) rods for screwing and aligning the module, respectively; (H) connectors; (I) screws. donor chamber works as a multifunctional device in which the sample is weighed and, after adjustment to other parts of the pervaporator, leaching, masking, and (bio)chemical derivatizing reactions take place in this chamber. Concerning the acceptor chamber, it also requires being inline coupled to a dynamic manifold for driving the pervaporated species to the detector. Even when the detector is integrated in this chamber, coupling with the continuous manifold is desirable in order to clean the chamber between input of samples. Derivatization reactions, preconcentration steps, etc., also require the continuous manifold–upper chamber arrangement. Discrimination between species can be based on this coupling.

The characteristic versatility of FI manifolds endows pervaporation with a very valuable aspect in separation techniques as preconcentration capability is. The location of the upper chamber in the loop of a conventional low-pressure injection valve enables the acceptor fluid to remain static during pervaporation by keeping this valve in its filling position. After a preset time, long enough for sufficient enrichment of the acceptor fluid in the pervaporated analyte, the valve is switched to the injection position and the stream leads the content of the loop to the detector. During the enrichment time, the acceptor fluid is continuously reaching the detector, thus establishing the baseline. When the detector is integrated with the

pervaporator through a probe (located at the top of the acceptor chamber, faced to the membrane), the presence of this valve allows monitoring of the mass transfer through the membrane, i.e., monitoring of the kinetics of the pervaporation process. Both types of dynamic manifold pervaporator for liquid and solid samples are shown in Figure 2.

## Pervaporation Efficiency

The efficiency of a pervaporation process can be done in relative terms, i.e., comparing the signals provided by the analyte (or its reaction product) under different experimental conditions, or in absolute terms, comparing the signal obtained under the working conditions with that corresponding to 100% mass transfer of the analyte. The first procedure is usually used in optimization experiments, and it does not require special alterations of the manifold. On the other hand, the absolute procedure requires the use of an auxiliary channel that directly leads the same sample volume as that used in the pervaporation process to the detector, in order to measure the signal corresponding to the whole amount of analyte, and compare it with the signal obtained from the channel coming from the acceptor chamber of the pervaporator, with the collected analyte. The comparison through the peak height is not valid as

**Figure 2** Continuous–discrete approach to implementing analytical pervaporation. The dotted line corresponds to a potential derivatization reaction of the pervaporated species, while the dashed lines represent the continuous manifold used for automatic insertion of liquid samples. the dispersion of the two plugs (that injected and that from the acceptor chamber) is different. Instead, comparison between peak areas must always be used.

## Variables Influencing Analytical Pervaporation

There are a series of variables influencing on the mass transfer process, which can be divided into two groups, depending on which part of the system is involved.

### Variables Pertaining to the Donor Chamber

**Temperature** An increase in temperature in the donor chamber, carried out either by immersing it into a water bath or with focused microwaves, increases the vapor pressure of the analyte and thus the mass transfer process.

**Sample agitation** Magnetic stirring helps the removal of gases from the donor stream, and so do ultrasounds in a more intense way; however, they are not recommended because of causing leakage and so losses of the gas phase.

The presence of chemically inert beads of a proper size in the donor chamber boosts the transfer of volatile species into the air gap, with both liquid and solid samples because the residence time, in the first instance, is increased due to the tortuous path that the liquid has to go through, and the beads separate the particles of solids, creating a larger surface for the removal of the gas from the sample to the air gap.

**Volume of the air gap** The smaller the gap is the smaller is the amount of analyte required to go through the membrane. The best way of decreasing the volume of the air gap (in liquid samples) is lengthening the waste line because it causes an overpressure in the donor chamber, which raises the level of the solution.

**Flow rate** In liquid samples, the flow rate affects the mass transfer process because the lower it is the longer is the residence time of the analyte in the lower part of the pervaporation unit. The flow can be stopped to allow steady-state mass transfer, but it decreases the sampling frequency, so a compromise between sensitivity and expediency is needed.

**Concentration of reagents** If the measurable volatile substance is a reaction product of the analyte of interest, the concentration of reagents and pH have a dramatic effect on the pervaporation process.

### Variables Pertaining to the Acceptor Chamber or Auxiliary Manifold

**Flow rate** As said before, the flow rate of the acceptor stream strongly affects the mass transfer equilibrium. The continuous use of fresh acceptor fluid maximizes the concentration gradient between the donor and the acceptor chamber. However, if keeping the acceptor fluid static during pervaporation is required, it has to be achieved by accommodating the acceptor chamber in the loop of an injection valve, as commented before. In the filling position, the acceptor stream passes through the bypass to the detector at a preset flow rate. Once the collection time has elapsed, the valve is switched to its load position and the stream passes through the loop to sweep its contents to the detector. The use of a valve is necessary because the direct stopping of the propulsion unit for the acceptor stream disturbs the detector baseline through the start-and-stop sequence, which in turn causes part of the fluid to return to the propulsion unit.

**Preconcentration of pervaporated analytes** The equilibrium between phases can be efficiently displaced by the continuous removal of the pervaporated species from the acceptor chamber, followed by their concentration, either in a minicolumn (packed with suitable material such as an ion exchanger or a sorbent) placed before the detector or in the flow-cell itself.

**Features of the membrane** The membrane thickness and pore size have a strong influence on the pervaporation process. Permeability is inversely proportional to the thickness of the membrane and directly proportional to its pore density. An increased membrane pore size can be expected to require a decreased pore density to ensure acceptable mechanical stability. As a result, the overall area of the pores through which gas diffusion takes place could even decrease with increasing pore size and lead to a lower permeability.

## The Physics of Analytical Pervaporation: Kinetics of the Mass Transfer Process

Monitoring the mass transfer kinetics is a key aspect in order to optimize pervaporation experiments. The main goals of the optimization are the identification of the influencing factors and the establishment of an appropriate pervaporation time to ensure a high throughput without an appreciable decrease in sensitivity. The kinetics of the mass transfer can be

monitored in two ways: (1) integrating pervaporation and detection in a single module, and (2) integrating, after the pervaporation process, a retention step with detection. The first option can be carried out placing either a probe-type sensor, electroanalytical or optical, inside the acceptor chamber, with the active surface faced to the membrane. The second way is achieved with a flow cell packed with a suitable material (ion exchanger or sorbent) and placed inside a nondestructive detector that quantifies the continuous retention of the pervaporated analyte or its reaction product.

## Analytical Features of Pervaporation Methods

The analytical features of pervaporation, concerning the basic analytical properties, namely, sensitivity, selectivity, and precision, strongly rely on experimental variables. Sometimes, a given variable can have an opposite effect on two of the analytical properties, so a compromise between them is needed.

### Sensitivity

The sensitivity of a method involving pervaporation depends mainly on the efficiency of the separation step. The efficiency of pervaporation can be adjusted in order to fit the signal obtained from the analyte or its reaction product to the linear portion of the calibration curve for a given method, thus avoiding the need for a dilution or concentration step.

The analytical signal can be optimized for the sake of quantitation acting on the influencing variables already mentioned: increasing the temperature of the donor chamber, stirring the sample, using chemically inert beads, employing optimal reagent concentrations, increasing the pervaporation time, using an efficient procedure for concentrating the volatile species, and increasing the amount of sample used.

When the concentrations of the target analytes in the sample exceed the upper limit of the linear range of the calibration curve, a dilution or pseudodilution step is mandatory in order to fit the unknown concentration to this portion of the calibration curve, and hence to increase the precision of the measurements. A series of alternatives to the usual previous dilution of the sample have been developed in order to avoid the errors involved in a dilution step or in the weighing of small amounts of a solid. These alternatives are: (1) using of a lower pervaporation temperature; (2) changing the chemical conditions to a less favorable situation if a derivatization reaction is required, in order to reduce the yield of the monitored species; (3) enlarging the air gap between the

sample and the membrane by the addition of the suitable number of spacers; (4) using a thicker membrane; (5) using a smaller loop for the injection valve (if the sample is a liquid); or (6) increasing the flow rate or the donor and/or the acceptor stream.

### Selectivity

The fact that pervaporation can only be used to separate volatile analytes may initially seem a shortcoming rather than an advantage; however, it results in increased selectivity for the target analytes and enables their determination in complex samples such as biological fluids and environmental specimens with no prior treatment, using pervaporation as a cleanup step. If the target analyte is not volatile but can be converted into a volatile substance by means of a selective (bio)chemical reaction, it can also be separated by pervaporation. The possibility of employing the derivatization reaction prior or after the separation step has extended the scope of pervaporation to a variety of analytes and allowed pervaporation units to be coupled to various detector types. Pervaporation can also be used for speciation analysis as it allows the selective determination of different forms of the target analyte.

In multideterminations, and also when the target volatile analytes possess different boiling points, the pervaporation unit can be used at different temperatures to achieve selective separation of the species of interest.

Discrimination between polar and nonpolar volatile analytes can be accomplished by using microwave irradiation of the donor chamber in order to promote the evaporation of polar species. Conventional heating can then evaporate nonpolar ones.

Selectivity can also be improved by changing the membrane used in the pervaporation process, owing to the fact that this property depends on the molecular dimensions of the permeated species.

### Precision

The fact that the placement or the passage of the sample in or through the donor chamber, respectively, which is quite reproducible by means of stirring or the use of chemically inert beads, results in highly reproducible signals following pervaporation.

Repeatability can also be improved by aspirating the detector waste at a flow rate identical to that of the acceptor stream. If a chemical reaction with an additional reagent is required, the flow rate of the detector waste has to be the same as the combined individual flow rates.

The use of long waste tubing in the lower part of the pervaporation module can also improve the

precision of the method since the pressure in the module increases and thus small variations in pressure caused by both internal and external noise have a smaller effect.

The use of gas diffusion membranes instead of ultrafiltration membranes can also improve the precision because the former are more resistant to bending than the latter; this avoids changes in the permeate flux resulting from both irreproducible membrane areas and increased volumes of the upper chamber.

## Scope of Application of Analytical Pervaporation

Analytical pervaporation can be used for the determination of one or more analytes. In multideterminations, analytes can be quantified sequentially or in a simultaneous way.

### Sample Types

The versatility of the design of an analytical pervaporation module, attributable to its changeable donor volume and the air gap present above the sample, has enabled its use with liquid, solid, and semisolid samples. **Table 1** summarizes the applications of analytical pervaporation and the main fields in which it has been used. The manifold used and the way in which the sample is introduced in the system vary depending on whether it is liquid or solid. The main difference between the treatment of liquid and solid samples is the fact that with liquids the whole pervaporation process, from sample introduction to delivery of the results can be fully automated, while some operator's intervention is needed when dealing with solids.

### Derivatization Reactions

The development of chemical or biochemical reactions widens the scope of analytical pervaporation, making possible the determination of nonvolatile species. These reactions can take place in both the donor and the acceptor chamber. In the first case the aim of the reaction is to achieve a volatile species from a nonvolatile analyte either injecting appropriate reagents or merging the donor and the reagents stream; in the second instance the objective is to adapt the monitored product to the characteristics of the detector and the most effective manner of doing so is using the solution containing the reagents as acceptor solution. In this way, the pervaporated analytes react on the acceptor side of the membrane, thus displacing the mass transfer equilibrium. Solid reagents, which are very common in enzyme-catalyzed reactions, are packed in a tube

placed between the injection valve and the donor chamber of the pervaporator.

### Integrated Pervaporation and Detection: Detector Types

The best way of monitoring pervaporated species is by inserting a probe-type sensor in the acceptor chamber with its active side facing the membrane. The most salient advantages of integrating pervaporation and detection are as follows:

1. The response time is shortened with respect to the conventional location of the sensor behind the separation module because there is no need to transport the analytes to the detector.
2. The kinetics of the mass transfer across the membrane can be monitored, obtaining a better understanding of the pervaporation process and an easier optimization.
3. The system is dramatically miniaturized, as the leaching, derivatization, separation, and detection steps take place in a single module.

Pervaporators are amenable to coupling to any type of detector via an appropriate interface such as a transport tube, a microcolumn packed with adsorptive or ion-exchange material, or a gas liquid separator. The acceptor stream can be either liquid or gaseous depending on the characteristics of the detector. The detectors most frequently used are the spectroscopic – atomic or molecular, electroanalytical (potentiometric, voltammetric), electron capture, and flame ionization types. The low selectivity of some of these detection techniques is overcome by that of the pervaporation step, endowing the overall analytical process with the selectivity required for the analysis of complex matrices. The potential use of the pervaporation technique for sample insertion into water-unfriendly detectors such as mass spectrometers or devices such as those based on microwave-induced plasma remains unexplored.

### Coupling a Pervaporator to a Gas Chromatograph: An Alternative to Headspace Sampling

The coupling of a pervaporator to a gas chromatograph is one of the most promising uses of pervaporation and is worth a more detailed discussion, because of the advantages that pervaporation presents as compared with both static and dynamic headspace sampling techniques. In the static approach, the sample is placed in a closed chamber and heated until the volatile compounds in the headspace reach the equilibrium with the sample. Then, part of

**Table 1** Applications of analytical pervaporation in different fields

Analyte	Sample	Derivatization reaction	Detection	Comments
<i>Environmental samples</i>

the vapor phase is injected in the chromatograph for analysis. The dynamic headspace or purge and trap mode requires the continuous removal of the gas phase from the chamber. Owing to the fact that the separation of the volatile analytes from the sample is a slow process, an intermediate trap is needed in order to concentrate the analytes before their introduction in the chromatograph.

Pervaporation provides a number of advantages versus headspace techniques that can be summarized as follows:

1. The thin air gap above the sample requires very small amounts of the analytes to establish equilibrium with the sample and the mass transfer across the membrane.

2. The continuous removal of the volatilized analytes displaces the equilibrium and increases the separation efficiency.
3. Continuous removal of the pervaporated analytes to the preconcentration column, if used, allows fresh portions of acceptor gas to come into contact with the diffused species, thus displacing the mass transfer equilibrium.
4. The separation step can be totally or partially automated (with liquid or solid samples, respectively) with minimal purchase and maintenance costs.
5. Unlike purge and trap, no water vapor condenser is required, nor is a hydrophobic sorbent, as no water crossing through the hydrophobic membrane occurs at the usual working temperatures.

## Prospects of Analytical Pervaporation

Pervaporation is a useful analytical tool that features simplicity, automation, and miniaturization capabilities. The actual potential of this technique for the analysis of solid, liquid, and slurry samples can be inferred from its intrinsic features and from available methods using a pervaporator.

Consolidation of this technique as an effective, widespread analytical tool needs the gathering of sufficient research experience to compile a cookbook of methods, where potential users can search for solutions to specific problems, and the commercialization of inexpensive pervaporation modules meeting the requirements of a variety of samples and analytes. Once these two aspects are developed, pervaporation can become a useful tool for routine

environmental, pharmaceutical, food, and industrial analyses.

safety concerns are mainly theoretical, the perception of risk remains very high and has led to initiatives to eliminate, reduce, or replace thiomersal in all vaccine presentations. In general, however, production and usage of organomercurials is declining.

At present, most studies are focused toward naturally formed organomercury compounds. By far the most common of these are the monomethylmercury compounds. The term 'methylmercury' is used throughout this text to represent monomethylmercury compounds. In many cases the complete identity of these compounds is not known except for the monomethylmercury cation,  $\text{CH}_3\text{Hg}^+$ , which is associated either with a simple anion, like chloride, or a large charged molecule (e.g., a protein).

Many of the environmental aspects of mercury and its compounds have been reviewed. During recent years, new analytical techniques, which have become available, have been used in environmental studies and the understanding of mercury chemistry in natural systems has improved significantly. Mercury can exist in a large number of different physical and chemical forms with a wide range of properties. Conversion between these different forms provides the basis for mercury's complex distribution pattern for local and global cycles, and for its biological enrichment and effects. The most important chemical forms are: elemental mercury ( $\text{Hg}^\circ$ ), divalent inorganic mercury ( $\text{Hg}^{2+}$ ), methylmercury ( $\text{CH}_3\text{Hg}^+$ ), and dimethylmercury ( $(\text{CH}_3)_2\text{Hg}$ ).

Once methylmercury is formed it enters the food chain by rapid diffusion and firm binding to proteins in aquatic biota and attains its highest concentrations in the tissues of fish at the top of the aquatic food chain due to biomagnification through the trophic levels. The main factors that affect the levels of methylmercury in fish are the diet/trophic level of the species, age of the fish, microbial activity and mercury concentration in the upper layer of the sediment, dissolved organic carbon (DOC) content, salinity, pH, and redox potential.

Extensive investigations have recently been conducted in Scandinavia and North America where it was discovered that the long-range transport of  $\text{Hg}^\circ$  and the potential role of acidification (through acid rain) have become major factors concerning future exposure of humans to methylmercury. As a result, methylmercury has exceeded regulatory safety limits in fish (0.5–1.0 mg per kg, fresh weight) in large numbers of remote lakes. Due to long-range transport and deposition high mercury concentrations were observed in communities in remote Northern environments that depend heavily upon mercury-contaminated local diets (fish, birds, marine mammals).

## Types of Compounds and Matrices

Concentrations of mercury in biological and environmental samples are relatively low except in mercury contaminated and industrial areas. Total mercury concentrations in some matrices are elsewhere in this encyclopedia. Only a very brief overview of the presence of organomercury compounds in various compartments of the environment is given below.

### Air

The major form of mercury in air is elemental mercury vapor ( $\text{Hg}^\circ$ ). Typical concentrations of mercury and its compounds in ambient air may range between 1 and 4  $\text{ng m}^{-3}$  for elemental mercury, from 1 to 50  $\text{pg m}^{-3}$  for reactive gaseous mercury (water-soluble gaseous mercury species) and total particulate mercury, whereas MeHg has been found in the range between 1 and 20  $\text{pg m}^{-3}$ . Volatile mercury(II) compounds represent a large part of total gaseous mercury in stack gases from coal burning power plants. Even though  $\text{Hg}^\circ$  and dimethylmercury are the most volatile forms of mercury, dimethylmercury has not unequivocally been detected in the atmosphere. Its presence was detected in gases from landfill waste sites. It is interesting to note that, although significant quantities of dimethylmercury may be emitted to the atmosphere, the lifetime of this species is short, owing to photochemical and/or chemical degradation to  $\text{Hg}^\circ$ . Reliable data on mercury species in air are still very limited and further analytical developments are needed.

### Water

Concentrations of total mercury in water samples are very low (in the nanogram per liter level or below), so that accurate analysis is still a major problem. The theoretical approach via stability calculations can be of great help in making rough estimates of the predominant mercury species under various conditions. Mercury compounds occurring in natural waters are most often defined by their ability to be reduced to elemental mercury. In lake waters methylmercury species account for 1–30% of total mercury. Most of the methylmercury is probably associated with dissolved organic carbon (DOC). Limited data are available on the formation constants between the methylmercury cation and DOC. Thiol groups ( $-\text{RSH}$ ) have been shown, however, to have a higher capability to bind methylmercury in comparison with ligands containing oxygen and nitrogen donor atoms and the inorganic ions ( $\text{CN}^-$ ,  $\text{Cl}^-$ ,  $\text{OH}^-$ ). Methylmercury compounds in surface runoff waters,

soil pore waters, and groundwaters are similar to the species in lake waters and are generally quite strongly associated with DOC. Dimethylmercury has rarely been reported in surface waters except in deep oceans and during some seasons in the slurry of salt marches. Mercury in seawater exists mainly in the form of  $\text{Hg}^{2+}$  complexed with  $\text{Cl}^-$  ions. Methylmercury concentrations in seawater are generally lower than in lake waters. Dissolved gaseous mercury vapor is also present in ocean waters.

### Sediments and Soils

Mercury in these two compartments of the environment is mainly associated with humic matter. Following methylation, methylmercury does not usually build up in sediments to more than  $\sim 1.5\%$  of the total mercury present. This appears to be an approximate equilibrium level between formation and removal. Methylation–demethylation reactions are assumed to be widespread in the environment and each ecosystem attains its own steady state with respect to the individual species of mercury. Dimethylmercury is considered to be unstable in sediments and is assumed to be stabilized by a conjunction of factors, such as high sulfide levels, salinity, anoxic conditions, and constant inputs of methane into the media. It is also important to note that sampling of sediment samples from anoxic/suboxic bottoms must be conducted with extreme care, as, in contrast, changes of environmental conditions (T, redox potential) during sampling may significantly influence the concentrations of mercury species and partitioning (see Sample Handling and Storage).

### Biota

The highest levels found in both fresh and marine organisms are found at the highest trophic levels, where mercury levels can exceed the ‘black list limit’ of 0.5 mg per kg. The percentage of methylmercury to total mercury in fish muscle varies from 80% to 100%, but in other organs its concentration is smaller (in liver and kidney up to 20%). In other aquatic organisms, the percentage of methylmercury is more variable, depending on water depth, locations, and the type of organism. Relatively high mercury and methylmercury concentrations have been reported for marine birds. Birds feeding on wild vegetation generally have much lower mercury in their bodies. There have recently been many studies performed on terrestrial ecosystems (particularly in Canada, Sweden, and the USA). Mercury also passes from vegetation into the food chains of the fauna.

### General Facts about Organomercury Compounds

The vapor pressure of  $\text{CH}_3\text{HgCl}$  is 1.13 Pa and the vapor pressure for dimethylmercury is several times higher. Mercurials also differ greatly in their solubility. The solubility in water increases in the order: mercurous chloride  $< \text{Hg}^\circ < \text{CH}_3\text{HgCl} < \text{HgCl}_2$ . Certain species of mercury are soluble in nonpolar solvents. This includes elemental mercury and halide compounds of arylmercurials.  $\text{CH}_3\text{Hg}^+$  occurs in aqueous solutions as an aqua complex  $\text{CH}_3\text{–Hg–OH}_2^+$  with a covalent bond between mercury and oxygen. The cation behaves as a ‘soft’ acid and has a strong preference for the addition of only one ligand.  $\text{CH}_3\text{Hg}^+$  undergoes rapid coordination reactions with sulfur, phosphorus, oxygen, nitrogen, halogens, and carbon. The rate of formation of  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{OH}^-$  complexes is extremely fast and is diffusion controlled. Methylmercury, like  $\text{Hg}^{2+}$ , forms strong bonds with sulfur, and it is very likely that all methylmercury in biota is bound to the sulfhydryl groups of proteins. The organomercury–sulfur bond is, however, much less stable than the inorganic Hg–S bond and can be easily cleaved in acid solutions of pH 1. This is used to liberate methylmercury from biological tissues prior to its analytical determination. The  $\text{CH}_3\text{Hg}^+$  unit itself is kinetically remarkably inert toward decomposition. Therefore, methylmercury compounds, once formed, are not readily demethylated. The neutral species derived from  $\text{CH}_3\text{Hg}^+$  can readily pass through both biological and nonbiological boundaries. This, together with the broad tendency to form stable complexes quickly (and the robustness of the  $\text{CH}_3\text{Hg}^+$  unit), enhances the toxicological properties of methylmercury. Like methylmercury, ethylmercury is an organic mercury compound, considered to have similar toxic properties to methylmercury. Ethylmercury is still used in vaccines and its commercial name is Thiomersal, also known as ‘thimerosal’. It has been used in very small amounts in vaccines since the 1930s to prevent bacterial and fungal contamination. It contains  $\sim 49\%$  ethylmercury. Unfortunately, there is a paucity of data on the metabolism, excretion, and toxicity of ethylmercury although there have been reports on toxicity following exposures.

### Sample Handling and Storage

The various sampling procedures must be appropriate to the sample type and methylmercury concentration. Organic mercury is present at much lower concentrations than total mercury, except in fish or seafood. Therefore, apart from the methylmercury-specific separation and detection techniques, careful

handling of samples prior to analysis is necessary. A general difference between total and organomercury analyses is that the contamination of samples by organomercurials prior to analysis is much less probable. They are not usually present at detectable levels in laboratory environments.

### Cleaning Procedures

Rigorous cleaning procedures must be used for all laboratoryware and other equipment, which comes into contact with samples. Reagents that are used for the analyses of total and organomercury species must be of suitable quality (preanalyzed and shown to contribute minimally to blanks). The best materials for sample storage and sample processing are Pyrex and silica (quartz) glass, and Teflon (PTFE or FEP). Plastics such as polypropylene are not recommended since these materials can contribute to either contamination or losses of mercury. There are several cleaning procedures that are recommended: (1) aqua regia treatment followed by soaking in dilute ( $\sim 5$ – $10\%$ ) nitric acid for a week; (2) soaking in a hot oxidizing mixture of  $\text{KMnO}_4$  and  $\text{K}_2\text{S}_2\text{O}_8$ , followed by  $\text{NH}_2\text{O} \cdot \text{HCl}$  rinsing and soaking for a week in  $5 \text{ mol l}^{-1} \text{ HNO}_3$ ; (3) soaking in a 1:1 mixture of concentrated chromic and nitric acids for few days; (4) soaking in  $\text{BrCl}$  (mixture of  $\text{HCl}$  and  $\text{KBrO}_3$ ); and (5) for Teflon, cleaning in hot concentrated  $\text{HNO}_3$  for 48 h, followed by soaking in dilute  $\text{HNO}_3$  ( $50\%$ ) (which is repeated twice). After such treatments, laboratoryware is usually rinsed with mercury-free deionized water or double distilled water, and stored in a mercury-free place, preferably sealed in mercury-free plastic bags. Some authors recommend storage in dilute ( $1\%$ ) hydrochloric acid until used. Laboratoryware that is used for methylmercury analyses should be prepared with extreme caution. It has been shown that final soaking (after using one of the above mentioned cleaning procedure) of laboratoryware, particularly Teflon, in hot ( $70^\circ\text{C}$ )  $1\%$   $\text{HCl}$  removes any oxidizing compounds (e.g., chlorine), which may subsequently destroy methylmercury in solution.

### Air

Most techniques employ sampling of large volumes of air through one or more media (solid or liquid sorbents) that trap the mercury species of interest. Therefore, one of the most critical parameters in obtaining accurate final results is the determination of the sample volume collected under standard conditions (of temperature and pressure). It is important to calibrate flow meters regularly. Usually a high degree of accuracy is achieved when sampling ambient

(indoor and outdoor) air. The presence of excessive amounts of water vapor and  $\text{CO}_2$  (e.g., in fuel or combustion gases) may necessitate a correction to the flow meter readings.

The first operational step is the removal of particulate matter, which is usually separated by glass fiber filters, Teflon or a plug of glass or quartz-wool. If selective adsorption methods (described later) are used, the first step is usually to separate mercury(II) compounds. Various adsorption materials have been used in the past. One of the most common is Chromosorb W, treated by  $\text{HCl}$  alone or coated with a polar stationary phase (e.g., OV-1 or SE-30). In recent years, methods for reactive gaseous mercury(II) compounds were validated and are based on mist chamber techniques, tubular and annular denuders. Following the trapping of mercury(II) species, a second trap is then used to collect methylmercury compounds. Chromosorb W, treated with  $\text{NaOH}$ , has been employed. The use of impingers with aqueous solutions and/or high-flow refluxing mist chambers has recently been optimized for the direct preconcentration of extremely low concentrations of methylmercury in ambient air. Methylmercury (and dimethylmercury if present) can also be trapped using Tenax or Carbotrap and cryogenic trapping followed by one of specific mercury instrumental technique.  $\text{Hg}^0$  is retained or captured on the final trap, usually consisting of silver- or gold-coated adsorbent. In most cases, the total gaseous mercury fraction in air is determined directly by noble metal amalgamation, or by other methods described in the previous section on inorganic mercury determination.

### Water

Collection and handling of aqueous samples for low-level determination of mercury must address factors such as whether the sample is representative of the system sampled, possible interconversion processes, contamination, as well as preservation and storage of the sample before analysis. The measurement (sampling and analysis) protocol must be even more carefully designed if speciation of mercury forms in aqueous samples is intended. There have been remarkable improvements in sampling and analytical techniques that have resulted in a dramatic increase in the reliability of data for mercury levels in water samples over the past 15 years. The stability of mercury in solution is affected by many factors. These include: (1) the concentration of mercury and its compounds, (2) the type of water sample, (3) the type of containers used, (4) the cleaning and pretreatment of the containers, and (5) the preservative added.

Contamination-free sampling devices (e.g., Teflon coated Go-Flo samplers) are commonly used. Alternatively, the water can be pumped through Teflon tubing using a peristaltic pump. Collection of surface waters is usually performed by hand, using arm-long plastic gloves. Samples are taken upwind of a rubber raft or a fiber glass boat. Precipitation samples can be collected by automatic samplers, with inline filtration if desired. Teflon wide-mouth jars have been favored for sampling waters with low mercury concentrations. Containers and other sampling equipment that come into contact with water samples should be made of borosilicate glass, Teflon, or silica glass. These materials have been found to be free from mercury contamination and therefore suitable for work at low, ambient levels. However, Teflon showed the best performance regarding both contamination- and loss-free storage of aqueous samples. The most volatile mercury forms possibly present in the water are  $\text{Hg}^0$  and dimethylmercury. They should be removed from the samples immediately after the sampling step by aeration (purging) with collection on Carbotrap or other suitable adsorption media for subsequent analyses in the laboratory.

Measurement of dissolved mercury compounds requires removal of particulate materials from the sample by either filtration or centrifugation. Various types of filters can be employed: 0.45  $\mu\text{m}$  membrane filters (precipitation, seawater), disposable polystyrene units (Nalgene) with nitrocellulose membrane filters, and pretreated glass fiber filters.

In order to store samples prior to analysis, samples should be preserved, generally by acidification. However, acidification is subject to two limitations: (1) suspended matter has to be removed prior to the acidification; and (2) dimethylmercury and  $\text{Hg}^0$  have to be removed prior acidification, otherwise conversion of these species into methylmercury and subsequently mercury(II), may occur. In general, samples for speciation of gaseous mercury species in water are processed immediately after sampling. However, if water samples do have to be stored for longer periods the mercury present may be stabilized by adding preservatives. For the analyses of organomercurials, preservation with oxidative reagents (as advised for total mercury analyses) should be avoided, since organomercurials are converted into inorganic mercury. Stabilization by  $\text{HNO}_3$  results in decreased methylmercury, while  $\text{Hg(II)}$  remains stable in the presence of this acid.  $\text{HCl}$  was found the most appropriate acid for storing aqueous methylmercury solutions. Sulfuric acid can also be used for preservation of methylmercury solutions in distilled water, although it is not suitable for natural water samples. Inorganic complexing agents, such as  $\text{Cl}^-$ ,

$\text{I}^-$ ,  $\text{CN}^-$ ,  $\text{Br}^-$ , and organic complexes (L-cystein) have also been proved to stabilize organomercury compounds in solution. Some authors claim that for methylmercury determinations, storage of unpreserved samples at low temperatures (or even deep-frozen) is better than adding acid.

### Biological Samples

Relatively little is known about the effects of storage on the stability of methylmercury in biological samples. Significant external contamination of samples with methylmercury is unlikely to occur; however, extreme precautions are necessary to avoid contamination by inorganic mercury.

Blood and hair samples are often analyzed in order to estimate exposure of humans to mercury and its compounds. Blood should be taken by venipuncture. Since some commercial containers may contain mercury compounds added as preservatives it is advisable to check each commercial batch before use. The samples should be refrigerated but not frozen, as it is sometimes useful to measure mercury in plasma and red blood cells separately. The separation of plasma and red blood cells should be performed as soon as possible to avoid hemolysis of the sample. If extensive hemolysis has occurred, the sample should be homogenized before an aliquot is taken for analysis. Blood samples may also be heparinized for total blood, serum, and red blood cell analyses. If unavoidable, samples may be stored deep frozen. However, repeatedly frozen and unfrozen blood samples showed a remarkable decrease in methylmercury concentrations. There is some evidence that methylmercury may be destroyed during lyophilization of blood samples.

Analysis of human hair offers several advantages over analysis of blood samples: e.g., ease of sampling and sample storage, the concentration of methylmercury is  $\sim 250$  times higher than in blood, and analysis of different longitudinal sections of hair can give information on the history of the exposure to methylmercury ingested through food. Adhering dust and grease should be removed by one of the following solvents: hexane, alcohol, acetone, water, diethylether, or detergents. IAEA and WHO recommend the use of only water and acetone. Long-term storage of human hair samples has shown that methylmercury is stable for a period of a few years if stored dry and in darkness at room temperature.

Biological samples are preferably analyzed fresh or after lyophilization. Deep freezing of fresh samples, especially with long storage, should be avoided, since it has been noticed that in some organisms methylmercury may decompose with repeated freezing and

unfreezing (particularly in bivalves). Methylmercury and total mercury in lyophilized biological samples, such as biological certified reference materials (CRMs), are stable for years. The CRMs are, however, sterilized either by autoclaving or by  $\gamma$ -irradiation. This important step prevents bacteriological activity, which may otherwise lead to methylation–demethylation processes. In general, very little is known on the effects of sterilization on the stability of methylmercury compounds. More studies are needed to investigate the stability of organomercury compounds in biological samples, particularly under various sample preparation and long-term storage conditions.

### Sediment and Soil

Sediment and soil samples should also be prepared with caution since the percentage of methylmercury in these samples is very low (e.g., <2% of total mercury) and improper handling and storage may lead to inaccurate results. These samples should be analyzed fresh or, if long-term storage is unavoidable, samples should be kept in the dark at low temperatures or freeze-dried. Drying at elevated temperatures (in the oven) results in high losses of total and methylmercury. Moreover, changes of pH, redox potential, moisture, etc., may significantly influence the stability of methylmercury in sediments. Due to changes during sampling, conversion of mercury species may occur (methylation, demethylation, reduction), particularly in the case of sediments taken from oxygen depleted bottom of water bodies. These samples should better be analyzed fresh or, if long-term storage is unavoidable, samples should be kept in the dark at low temperature, inert atmosphere, and deep frozen.

### Calibration Standards

There have been quite a few studies performed concerning the stability of organomercurials in standard solutions. A decrease of methylmercury in water solutions can be caused by adsorption onto the container walls or decomposition to Hg(II), Hg<sup>0</sup>, or (CH<sub>3</sub>)<sub>2</sub>Hg. Losses of methylmercury chloride due to volatilization is unlikely to occur ( $K_d$  (gas–liquid distribution coefficient:  $C_{\text{gas}}/C_{\text{H}_2\text{O}}$ ) is  $1.07 \times 10^{-5}$  at 20°C). The stability is strongly dependent on the concentration, the container materials, and the storage temperature. An aqueous methylmercury concentration of  $10 \mu\text{g l}^{-1}$ , stored in Pyrex glass (precleaned with HNO<sub>3</sub>) at low temperature (e.g., in a refrigerator) is stable for ~1 month. If Teflon containers are used, the solution is stable for several months if stored in the dark at room temperature. Some authors

recommend storage of methylmercury solutions in 0.2–0.5% HCl. Methylmercury standard solutions in organic solvents stored in Pyrex glass bottles (for gas chromatography (GC) analyses) are even more stable than water solutions.

Calibration standards may also be prepared in the gas phase. Elemental mercury vapor is often used for calibration of detectors for elemental or total mercury determination through preconcentration by amalgamation. Volatile organomercury compounds could also be prepared in the gas phase. This is of importance for the optimization of methodologies for organomercury speciation in air. An aliquot of vapor is removed from a temperature-stabilized vessel using a gas tight syringe. The concentration can be calculated from data on the partial pressure of the individual compounds and the gas-law equation. Calibration standards for inorganic mercury can also be ordered from major producers of CRMs.

## Analytical Methods

During the last 20 years, hundreds of papers dealing with determinations of organomercury compounds in environmental samples have been published. Most of them are based on the method originally developed by Westöö. In recent years, however, significant improvements of analytical methods in terms of specificity and sensitivity have been developed. This has allowed the determination of mercury speciation in all environmental compartments. Only a brief overview is given of methods that have been reported in review articles. Instead, particular emphasis has been placed on more recent analytical developments and future needs.

### Air

The concentration of total mercury in air can be determined with high precision and accuracy. There are still, however, analytical problems in separating and analyzing all the specific mercury compounds that can be present in air. Since concentrations of organomercurials are so low, a preconcentration step has to be employed. In general, two approaches are possible for measurements of mercury compounds in air: (1) Selective adsorption methods (usually coupled with nonselective detectors), in which the separation is operationally defined and a true species identification is not obtained (therefore it is not clear whether the species determined are the actual mercury compounds present in the atmosphere). (2) Gas chromatographic methods, which allow identification of various organic species by their unique retention times and specific mercury detection system. The

most readily determined forms are  $\text{Hg}^\circ$  and dimethylmercury, as these are the most volatile and non-polar species. Water vapor does not disturb their speciation and analysis. More problematic is the separation of methylmercury and mercury(II) compounds, where water vapor affects both the isolation and measurement steps. From the publications cited in the review article of Schroeder it is evident that in studies where selective adsorption methods are used, a maximum of four mercury species ( $\text{Hg}^\circ$ ,  $\text{Hg(II)}$ , monomethyl mercury, and dimethylmercury) are reported. In studies where GC separations are used, only  $\text{Hg}^\circ$ , monomethyl-, and dimethylmercury are reported, although total mercury is usually determined separately. The main difference between these approaches is the identification of  $\text{Hg(II)}$  compounds. The effect of moisture on the performance of the above-mentioned adsorption techniques has been addressed by many authors, although the problem has not, as yet, been solved completely. There is a big risk of  $\text{Hg}^\circ + \text{O}_3$  reaction in sampling bubblers or traps, which may result in too high  $\text{Hg(II)}$  values.

Improvements have been made recently for the preconcentration of gaseous methylmercury in air by preconcentration in mist chambers and subsequent determination by aqueous-phase ethylation, precollection on carbotrap columns, separation by GC, and detection by cold vapor atomic fluorescence spectrometry (CV-AFS). In order to understand the behavior and fate of mercury compounds in the atmosphere and their role in environmental mercury cycling, there is an urgent need for further development of analytical methods to afford identification of mercury species in the atmosphere by compound-specific analytical methods (as opposed to operationally defined protocols).

## Water

Only a few analytical techniques have been developed so far for the reliable determination of organomercury species in water samples. In many studies, mercury compounds in aquatic environments are speciated according to their ability to be reduced to the elemental state. Dimethylmercury and  $\text{Hg}^\circ$  (the most volatile mercury compounds) can be isolated by aeration and adsorption on a suitable adsorbent (dimethylmercury on Carbotrap or Tenax and  $\text{Hg}^\circ$  on gold trap) or by cryotrapping, or coupled with noble metal amalgamation (for  $\text{Hg}^\circ$ ), immediately after sampling. Alternatively, they can be directly analyzed by separation on GC columns and detected by one or more suitable mercury detectors. Samples should not be acidified prior to such separations since dimethylmercury and  $\text{Hg}^\circ$  are transformed into

methylmercury and  $\text{Hg(II)}$ , respectively. For specific organomercury compound determinations, a pre-separation and preconcentration method, followed by a very sensitive detection system, is necessary. In a typical extraction method,  $\text{CH}_3\text{HgX}$  (X is a halide ion) is extracted into an organic solvent (benzene or toluene) after acidification. This is followed by derivatization to a water-soluble adduct of methylmercury-cysteine, which is extracted into a water phase. After acidification,  $\text{CH}_3\text{HgX}$  is back-extracted into small amount of organic solvent. An aliquot is then injected onto a gas-liquid chromatography (GLC) column and detected by an electron-capture detector (ECD) or any other suitably sensitive detector (such as a plasma emission detector). Packed or capillary columns can be used. More precise descriptions of the chromatographic conditions are given later. There are quite a few modifications to this extraction procedure. For example, the methylmercury-cysteine compound may be transferred into dithizone chloroform solution and quantified by atomic absorption spectrometry (AAS). Inorganic and organic mercury species can be preconcentrated on dithiocarbamate or sulfhydryl cotton-fiber adsorbent that is then extracted as described above. The common drawbacks of most of these extraction procedures are the large sample requirements, low extraction yields, and nonspecific separation of dimethylmercury, if present.

There are also methods for determination of 'total' organomercury compounds. Inorganic and organic mercury are preconcentrated on a dithiocarbamate resin and are subsequently eluted with thiourea. Separation of organic and inorganic mercury is achieved by differential reduction and detection by CV-AAS. Inorganic and organic mercury can also be separated using anion-exchange resins. Organic mercury is then decomposed (by ultraviolet (UV) irradiation) and measured by CV-AAS. It has, however, been shown that the levels obtained by this method do not necessarily correspond to methylmercury (owing to the lack of specificity of the protocol). The method has recently been improved by the introduction of more specific separations of organic and inorganic mercury species by water vapor distillation.

Another method is based on aqueous-phase ethylation, room-temperature precollection, and separation by GC with CV-AFS detection. Modification of this method is frequently used in laboratories involved in studies of the biogeochemical cycle of mercury. Ionic mercury species in the sample are ethylated according to the following reactions:

Ethylated mercury species are volatile and can therefore be purged from solution at room temperature and then collected on adsorbent materials such as Carbotrap or Tenax. After thermal release, individual mercury compounds are separated by cryogenic or isothermal GC. As the species are eluted they are thermally decomposed (pyrolyzed) at 900°C and measured as  $\text{Hg}^0$  using a CV-AFS detector, which achieves very low detection limits ( $< 10^{-12}$  g). A CV-AAS detector can also be used with poorer limit of detection. In recent years, inductively coupled plasma-mass spectrometry (ICP-MS) is more and more frequently used as it offers numerous advantages over AAS and AFS detectors. Instead of ethylation, propylation was recently shown to be an even more suitable derivatization method, being free from interferences caused by halide ions. Hydration has also proven to be a useful derivatization method, in particular when coupled with preconcentration by cryotrapping.

In any case, the critical part of this procedure is the preparation of samples prior to derivatization. Methylmercury compounds must be removed from bound sites to facilitate the ethylation reaction. Interfering compounds (such as sulfides) must also be removed. Two approaches have so far been used. The first is based on extraction of methylmercury compounds into methylene chloride and then back-extraction into water by solvent evaporation. The second is based on water vapor distillation. Distillation has advantages since it quantitatively releases methylmercury from sulfur and organic-rich water samples. This approach has been proposed for standardization by the USEPA.

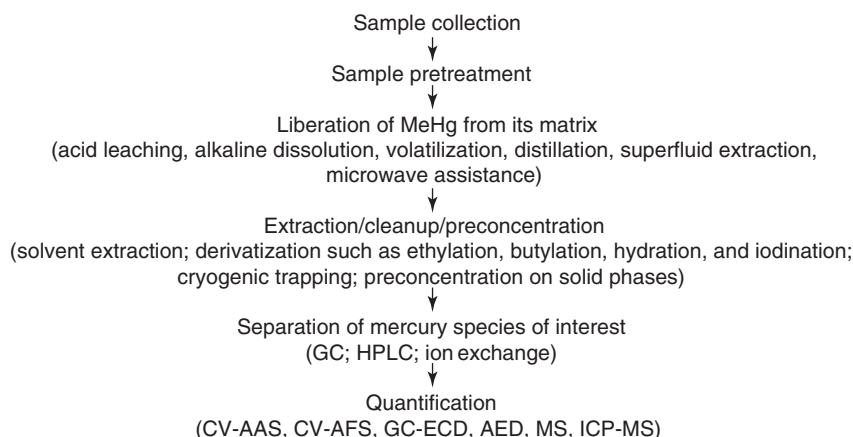

The analysis of different mercury compounds at environmental concentrations should be developed

further. Reliable data can be obtained for monomethyl mercury compounds and dimethylmercury. There is, however, a need to identify biogeochemically important mercury fractions that are currently measured by operationally defined rather than direct ('analytically rigorous') protocols.

### Other Environmental Samples

In general, methods are classified according to the isolation technique and the detection system. Most methods for the isolation/separation of organomercury compounds have been based on solvent extraction, differential reduction, difference calculations between 'total' and 'ionic' mercury, derivatization, or with paper- and thin-layer chromatography (TLC). The most common approaches to organomercury separation and detection are schematically presented in Figure 1.

**Extraction and GC determination** The basis of most present methods was introduced by Japanese and Scandinavian workers. It involves the extraction of organomercury chloride from acidified homogeneous samples into benzene (however, the use of toluene is strongly recommended for health and safety reasons). Organomercury compounds are then back-extracted into an aqueous cysteine solution. The aqueous solution is then acidified and organomercury compounds are reextracted with benzene or toluene. This double partitioning enables removal of many interferents (e.g., benzene-soluble thiols). Finally, methylmercury is analyzed by GC with electron-capture detection. Several modifications have been made to this protocol for the separation and identification of organic mercury in biological and other samples. For example, in the initial step the

**Figure 1** Steps for determination of organomercury compounds. CV-AAS, cold vapor-atomic absorption spectrometry; CV-AFS, cold vapor-atomic fluorescence spectrometry; GC, gas chromatography; GC-ECD, gas chromatography-electron capture detection; AED, atomic emission detector; ICP-MS, inductively coupled plasma-mass spectrometry; HPLC, high-performance liquid chromatography.

addition of copper(II) ions (or mercury(II)) enhances the removal of mercury bound to sulfur. Copper(II) was found superior to mercury(II) since it avoided problems of decomposing dimethylmercury, if present. However, inorganic mercury cannot be determined by this procedure, unless a reagent is added to form, for example, alkyl and aryl derivatives, which can then be extracted and determined by GC. In general, solvent extraction procedures are time consuming, corrections for the recovery of the procedure vary from sample to sample, and with some sample types (e.g., those rich in lipids) phases are difficult to separate due to the presence of persistent emulsions, particularly during the separation of the aqueous cysteine phase. To overcome these problems methylmercury can be adsorbed on cysteine paper (instead of into cysteine solution) during the cleanup stage. Using additional pre-separations prior to extraction, such as volatilization of methylmercury in a microdiffusion cell and distillation may also facilitate separation of phases during extraction.

When speciation is required with insoluble samples (such as sediments and soils), it is difficult to estimate recovery. In such samples, spiked methylmercury is not equivalent to the methylmercury originally present. By comparing various isolation techniques for methylmercury compounds in sediment samples and soils it has been shown that conventional methods based on acid leaching of organomercury compounds prior to extraction of methylmercury compounds into an organic solvent is inadequate in most cases to release methylmercury from sediment samples. Improved recoveries have been achieved by extraction of methylmercury by nitric acid at elevated temperature or assisted by microwave energy. It is important to mention that some protocols may lead to artifact methylmercury production, especially in procedures where methylmercury is isolated at higher temperatures. Quality of the results should therefore be regularly checked by the use of appropriate reference materials, if available or by comparison of the results between the laboratories and/or different analytical approaches.

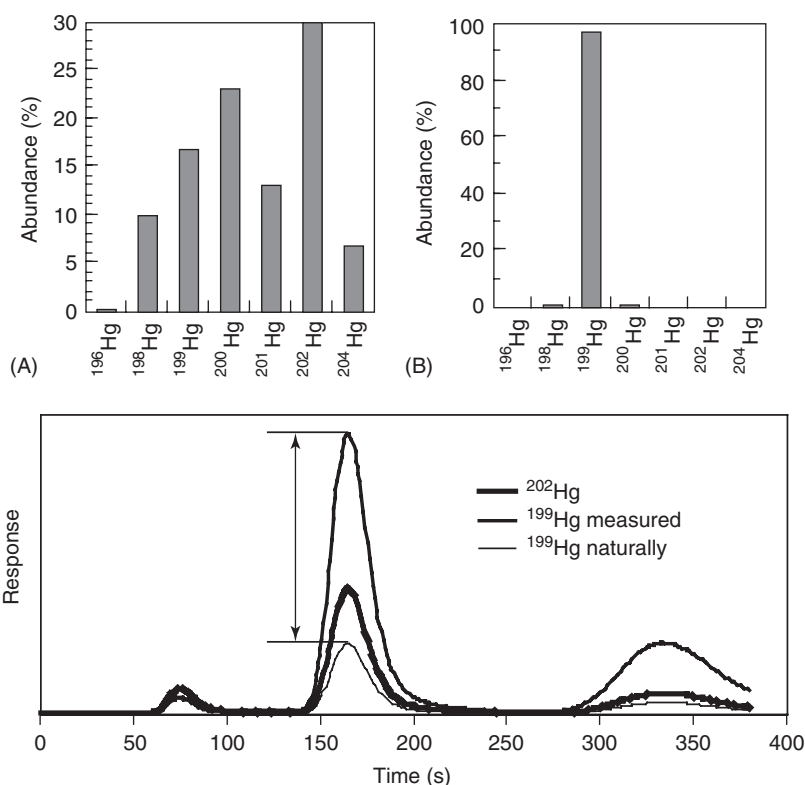

**Chromatographic conditions** Apart from the above-mentioned problems associated with the extraction of organomercurials, problems also exist in the chromatography of organomercurial halides. Many investigations have recommended that columns packed with 5% DEGS-PS on 100–120 mesh Supelcoport be used. Some other polar stationary phases have also been employed, e.g., PEGS, Carbowax 20 M, Durapak, Carbowax 400, PDEAS, HIEFF-2AP, etc. In order to prevent ion-exchange and adsorption processes on the column (which cause

undesirable effects such as tailing, changing of the retention time, and decrease of peak areas/heights), passivation of packing material is needed with Hg(II)chloride in benzene. Although the more inert nature of capillary columns would be expected to minimize such effects, improved chromatographic performance over packed columns cannot be readily achieved. Some workers still prefer to use packed columns since the analytical protocols using capillary columns require additional research to optimize performance.

Several workers have chosen to derivatize the mercury species to their corresponding nonpolar, alkylated analogs such as butyl derivatives, which can then be separated on nonpolar packed or capillary columns.

**Detectors** Various detectors can be used in combination with GC for the determination of mercury species. An ECD is a sensitive detector with an absolute detection limit of a few picograms. It does not, however, measure mercury directly, but responds to the halide ion attached to the  $\text{CH}_3\text{Hg}^+$  ion. The identification of small methylmercury peaks can sometimes be subject to a positive systematic error owing to coeluting contaminants. The use of a plasma atomic emission detector, a mass spectrometric detector, CV-AAS, CV-AFS, or ICP-MS can avoid such problems, since mercury is measured directly.

In recent times, the use of ICP-MS has become more widely used as a powerful tool for mercury speciation. Introducing mercury in the form of gaseous species into a dry plasma greatly reduces memory effects, achieving absolute detection limits of less than 100 pg of Hg. Based on the principle of isotope dilution, ICP-MS is characterized as a very precise and accurate analytical method. Equally important, multiple stable tracer experiments allow studies of the fate of Hg species in the environment and in biological systems. This concept allows the investigation of multiple transformation processes simultaneously. A simplified principle is presented in **Figure 2**. The isotope pattern of ambient Hg is presented in **Figure 2A** and the composition of a typical isotope enriched solution ( $^{199}\text{Hg}^{2+}$ ) in **Figure 2B**. The isotope pattern of the inorganic mercury in the sediment will be changed by adding such solutions into the sample. **Figure 2** also represents a GC-ICP-MS chromatogram of a sediment extract from methylation assay. The concentration of  $\text{CH}_3^{199}\text{Hg}^+$  is enriched in the sample relative to the fraction of  $\text{CH}_3^{199}\text{Hg}^+$  in the original sample and the magnitude of relative change relates to the amount of  $^{199}\text{Hg}^{2+}$  methylated.

**Figure 2** Top: Hg isotope abundance in nature (A) and <sup>199</sup>Hg tracer solution (B). Bottom: GC-ICP-MS chromatogram of a sediment extract after incubation with <sup>199</sup>Hg(II) showing the relative increase in the CH<sub>3</sub><sup>199</sup>Hg<sup>+</sup> signal.

**Derivatization methods** Many methods use the formation of volatile organomercury derivatives (through ethylation, butylation, hydration, and iodination) in order to separate them from the bulk of the sample by simple room-temperature aeration. The same ethylation method as described for water samples has also been applied to biological and sediment samples. An aliquot of alkaline digested sample or a distilled sample is subjected to ethylation by sodium tetraethylborate. Methylmercury is transformed into methylethylmercury and mercury(II) is transformed into diethylmercury. Both species can be determined simultaneously. Volatile ethylated mercury compounds, as well as elemental and dimethylmercury, are removed from solution by aeration and are then trapped on an adsorbent (Carbotrap or Tenax). Mercury compounds are separated on a GC column and pyrolyzed to elemental Hg<sup>0</sup> at 900°C for subsequent mercury determination by CV-AFS, CV-AAS, or ICP-MS. As mentioned previously, very low detection limits may be achieved by CV-AFS and ICP-MS, particularly if methylmercury is pre-separated by distillation (6 pg l<sup>-1</sup> for water and 1 pg g<sup>-1</sup> for biota and sediment samples). Instead of sodium tetraethylborate, sodium borohydride may also be used to form volatile methylmercury hydride, which is then quantified by GC in line with a Fourier

transform infrared spectrophotometer. The CH<sub>3</sub>I formed in a headspace vial may also be introduced onto a GC column and detected by microwave-induced plasma atomic emission spectrometry or AFS detectors. Propylation and hydration has also been applied with great success as described above.

**Differential reduction** There are also a few methods that are based on differential reduction. In the method developed by Magos, the inorganic mercury in an alkaline digested sample is selectively reduced by stannous chloride while organomercury compounds are reduced to elemental mercury by a stannous chloride-cadmium chloride combination. Elemental mercury released can be measured by CV-AAS. The method has been successfully applied for biological samples in toxicological, epidemiological, and clinical studies. CV-AAS has also been used for detection of organomercury compounds after pre-separation of organomercury by (1) anion exchange, (2) volatilization and trapping on cysteine paper, and (3) water vapor distillation. Organomercury compounds have to be destroyed by either UV irradiation or acid digestion prior to detection by CV-AAS. In most biological samples, the organomercury concentrations usually correspond to methylmercury. In some environmental samples such as sediment,

soil, and water samples, the concentrations of organic mercury (particularly if separated by anion exchange) have been found to be much higher than those of methylmercury compounds. This is probably due to the presence of some other organic mercury compounds that have not, as yet, been identified.

**Miscellaneous methods** The first practical method for differentiating between organic and inorganic mercury was a colorimetric method. Organomercury compounds were extracted into an organic solvent and determined spectrophotometrically as dithizone complexes. The method basically suffers from low sensitivity. High-performance liquid chromatography (HPLC) has proven to be of use with reductive amperometric electrochemical detection, UV detection, ICP-AES detection, or AAS detection. Neutron activation analysis has been used for methylmercury determinations in fish, blood, and hair samples after suitable pre-separation procedures. Graphite furnace AAS has also been used for the final determination of methylmercury in toluene extracts to which dithizone was added. An anodic stripping voltammetry technique has been developed for determination of methylmercury. However, the method has never been used for environmental samples. Methylmercury has also been extracted into dichloromethane. This was then evaporated down to 0.1 ml and subjected to GC with an atmospheric pressure active nitrogen detector.

An enzymatic method for specific detection of organomercurials in bacterial cultures has also been developed. It is based on the specific conversion of methylmercury (no other methylmetallo groups are enzymatically converted) to methane by organomercurial lyase. Ethyl- and phenylmercury can also be detected by this procedure.

### Determination of Other Organomercurials

Among organomercury species currently of interest, ethylmercury (EtHg) is a compound that requires further attention as it is still used in Thiomersal for preservation of vaccines. It is important to analyze ethylmercury in vaccines, in wastewater from waste treatment plants in industries using ethylmercury, as well biological samples in order to understand ethylmercury uptake, distribution, excretion, and effects. In principle, methods developed for methylmercury can also be used for ethylmercury, except in the protocols using derivatization by ethylation. In such cases propylation is recommended.

Only a few investigations concerning the determination of other organomercurials used in agricultural and for other purposes (see Table 1) have been

reported. Methoxyethyl- and ethoxyethylmercury have been examined by TLC and GC. It would appear that the only method that can separate and measure many of the compounds simultaneously is HPLC with UV detection. It offers several advantages. The separation of the compounds is performed at ambient temperatures; hence, thermal decomposition of the compounds does not occur. It offers the possibility to separate less volatile or nonvolatile species such as mersalylic acid or the aromatic organomercurials, which usually present a problem for GC. It is, however, very important to isolate these compounds from the environmental samples quantitatively. Methyl- and ethylmercury can easily be isolated from soils by extraction from acidified samples. Several extraction agents have been tested in order to release organomercurials from soils. Methyl- and phenylmercury can be extracted by potassium iodide–ascorbic acid and oxalic acids with satisfactory yields, whereas ethylmercury is only partly extracted. No suitable extraction techniques have been found for methoxyethyl- and ethoxyethylmercury in soils (due to decomposition of these compounds under acidic conditions).

### Toxicological Considerations

Organic mercury compounds are extremely toxic. Direct contact with skin can lead to fatal effects. Precaution during handling of this substance is absolutely necessary. It must, therefore, be handled in glove boxes to avoid inhalation, and gloves as well as other protecting clothes must be worn.

The general population is primarily exposed to methylmercury through the diet, particularly fish and fish products are the dominant source. As a preventive measure, WHO recommends the monitoring of hair levels of methylmercury in women of child-bearing age who consume large amounts of fish (e.g., 100 g per day or more). If the results of such monitoring activities indicate excessive exposure to methylmercury, appropriate and practical measures such as dietary changes should be introduced to reduce exposure, and to maintain it below internationally recommended allowable intakes.

## Introduction

Over the last two decades, capillary electrophoresis (CE) has been developed as a powerful separation technique for complex mixtures. Its advantages include a high separation efficiency, short analysis time, small sample requirement, and applicability to a wide range of analytes. The basic modes of CE that are presently being exploited include capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC), capillary isotachopheresis, capillary isoelectric focusing, and capillary gel electrophoresis.

In CZE, only ionic or charged analytes can be separated in principle since its separation mechanism is based on the difference in electrophoretic mobility of the analytes. MEKC has become popular as a powerful technique for the separation not only of neutral analytes but also of charged ones using a conventional CE instrument without any alteration. In MEKC, an ionic surfactant micelle is used as a pseudostationary phase (PS) that corresponds to the stationary phase in conventional chromatography and the surrounding aqueous phase to the mobile phase. The separation principle of MEKC is based on differential partitioning of analytes between the aqueous phase and the micelle phase.

MEKC is a mode of electrokinetic chromatography (EKC) in which surfactants (micelles) are added to the buffer solution. They have polar head groups that can be cationic, anionic, neutral, or zwitterionic and nonpolar hydrocarbon tails. The formation of micelles is a direct consequence of the hydrophobic effect. The surfactant molecules can self-aggregate if the surfactant concentration exceeds a critical micelle concentration (CMC). The hydrocarbon tails will then be oriented toward the center of the aggregated molecules, whereas the polar head groups point outward. Micellar solutions can solubilize hydrophobic compounds that would otherwise be insoluble in water. Every surfactant has a characteristic CMC and aggregation number (AN), i.e., the number of surfactant molecules making up a micelle (typically in the range of 50–100) (see also Table 1). The size of the

micelles is in the range of 3–6 nm in diameter; therefore, micellar solutions exhibit properties of homogeneous solutions. Micelles have a dynamic structure that is the result of the rapid equilibrium between aggregated and monomeric forms. It is the differences in interaction between the micelle and the neutral solute that cause the separation. Micellar solutions have been employed in a variety of separations and spectroscopic techniques.

## Micelles as Pseudostationary Phase for MEKC

The CMCs and ANs of various kinds of surfactants suitable for PSs in MEKC are listed in Table 1. An anionic surfactant, sodium dodecyl sulfate (SDS), is most widely used as a PS in MEKC. Its popularity can be attributed to its low CMC, high aqueous solubility, low Krafft point, ready availability and the low cost of the pure product.

Cationic surfactants such as tetradecyltrimethylammonium bromide (TTAB), cetyltrimethylammonium bromide (CTAB), and cetyltrimethylammonium chloride (CTAC) have also been useful for MEKC analysis. Most cationic surfactants have an alkyltrimethylammonium group, and their counterions are halides. The addition of cationic surfactants to the background electrolytes (BGE) caused the reversal of electroosmotic flow (EOF) owing to a positively charged capillary wall on account of the adsorption of cationic surfactants. As a result of the reversed EOF, the polarity of the electrodes has to be reversed in order to detect the analytes.

Nonionic surfactants themselves do not possess electrophoretic mobility, but they have the distinct advantage of not contributing appreciably to Joule heating; hence, they may be used at high concentrations. They can have a great influence on the separation of charged analytes and can also be employed as PSs in mixed micelles with ionic surfactants. Nonionic surfactants such as polyoxyethylene (23) dodecyl ether (Brij 35), and polyoxyethylene (20) sorbitan monolaurate (Tween 20) have been effectively used as PSs for the separation of charged compounds through MEKC.

Zwitterionic surfactants are not widely used in MEKC. However, zwitterionic surfactants will be interesting if they are used in mixed micelles or as a modifier of the micelle because they should show

significantly different selectivities from other types of surfactants.

Macromolecular surfactants or high-molecular-mass surfactants (HMMS), butyl acrylate–butyl methacrylate–methacrylic acid copolymers (BMMAs), and sodium 10-undecylenate (SUA) oligomer have been introduced as PSs for MEKC. Since a HMMS forms a molecular micelle, which consists of one molecule, and the CMC value is essentially zero, one can expect a higher reproducibility in a HMMS–MEKC system compared with a low molecular mass surfactant (LMMS)–MEKC system.

Bile salts are biological surfactants synthesized in the liver. The bile salts have both a hydrophilic and a hydrophobic face and tend to combine together at the hydrophobic face in an aqueous phase. To improve selectivity, various types of bile salts have been used as PSs in MEKC. **Figure 1** shows the separation and determination of the ingredients of a cold medicine through MEKC with bile salt.

Although they are not micelles, microemulsions and cyclodextrin (CD) derivatives have also been introduced as PSs for MEKC. Oil-in-water (o/w) microemulsions have been shown to be good PSs for EKC. Microemulsions (o/w) are prepared by mixing oil, water, a surfactant, and a cosurfactant such as a medium alkyl-chain alcohol. They have the characteristic properties of a solvent, such as thermodynamic stability and a high solubilization power. The

structure of the o/w microemulsion is similar to that of the micelle, except that the microemulsion has a core of a minute droplet of oil. The surfactant and the cosurfactant are located on the surface of the oil droplet to stabilize it. The separation basis of microemulsion EKC (MEEKC) is similar to that involved in MEKC. CD has been widely used not only in liquid chromatography but also in CE as a mobile phase modifier. The use of CD is particularly effective for the separation of aromatic isomers and enantiomers.

## Fundamentals

### Separation Principle

**Figure 2** illustrates a schematic representation of the separation principle of MEKC. When an anionic surfactant such as SDS is employed, the micelle migrates toward the anode by electrophoresis. The EOF transports the bulk solution toward the cathode due to the negative charge on the surface of fused silica. The EOF is usually stronger than the electrophoretic migration of the micelle under neutral or alkaline conditions, and therefore, the anionic micelle also travels toward the cathode at a retarded velocity.

When a neutral analyte is injected into the micelle solution, a fraction of it is incorporated into the micelle and it migrates at the velocity of the micelle.

**Figure 1** Separation of 14 ingredients through MEKC using bile salt. Buffer,  $0.02 \text{ mol l}^{-1}$  phosphate–borate (pH 9.0) containing  $0.05 \text{ mol l}^{-1}$  sodium deoxycholate; applied voltage, +20 V; temperature, ambient; detection wavelength, 210 nm. Solutes: 1, caffeine; 2, acetaminophen; 3, sulpyrin; 4, trimetoquinol hydrochloride; 5, guaifenesin; 6, naproxen; 7, ethenzamide; 8, phenacetin; 9, isopropylantipyrine; 10, noscapine; 11, chlorpheniramine maleate; 12, tipecidine hibenazate; 13, dibucaine hydrochloride; 14, triprolidine hydrochloride. **Figure 2** Schematic illustration of the separation principle of MEKC.

**Figure 3** Schematic diagram of the zone separation in MEKC (A) and chromatogram (B).

The remaining fraction of the analyte migrates at the velocity of the EOF, and thus the migration velocity of the analyte depends upon the distribution coefficient between the micellar and the nonmicellar (aqueous) phases. The greater the percentage of analyte that is distributed into the micelle, the slower it migrates. The analyte must migrate at a velocity between the electroosmotic velocity and the velocity of the micelle (see **Figure 3**), provided the analyte is electrically neutral. In other words, the migration time of the analyte,  $t_R$ , is limited between the migration time of the bulk solution,  $t_0$ , and that of the micelle,  $t_{mc}$ . This is often referred to in the literature as the migration time window in MEKC.

### Retention Factor

The retention factor,  $k$ , is defined as the ratio of the number of analytes incorporated into the micelle,  $n_{mc}$ , and that in the surrounding aqueous solution,  $n_{aq}$ :

$$k = \frac{n_{mc}}{n_{aq}} \quad [1]$$

We can obtain the relation between the retention factor and migration time for an electrically neutral analyte as

$$k = \frac{t_R - t_0}{t_0 \cdot (1 - (t_R/t_{mc}))} \quad [2]$$

It can be rewritten as

$$t_R = \frac{1 + k}{1 + (t_0/t_{mc}) \cdot k} \cdot t_0 \quad [3]$$

When the migration time of the micelle is infinite or the micelle does not migrate in the capillary at all,  $t_0/t_{mc}$  will be zero; then eqns [2] and [3] become identical to those for conventional chromatography,

eqns [4] and [5]:

$$k = \frac{t_R - t_0}{t_0} \quad [4]$$

$$t_R = (1 + k) \cdot t_0 \quad [5]$$

In conventional chromatography,  $k = \infty$  means that the solute is totally retained in the stationary phase and is not eluted at all or the retention time becomes infinite, whereas in MEKC  $k = \infty$  means that the migration time of the solute,  $t_R$ , is equal to  $t_{mc}$ . In that case, such a solute migrates at the same velocity as the micelle or at the lowest velocity and is then detected last.

When  $t_0 = 0$  or the EOF is completely suppressed, eqn [3] becomes

$$t_R = \left(1 + \frac{1}{k}\right) \cdot t_{mc} \quad [6]$$

In this case, the surrounding aqueous phase remains stationary in the capillary and the micelle migrates toward the anode by electrophoresis.

Calculation of the retention factor using eqn [2] requires knowledge of  $t_0$ ,  $t_R$ , and  $t_{mc}$ . For the EOF marker of  $t_0$ , methanol is often used since the distribution coefficient for methanol between the micelle and aqueous phases is negligibly small. Although methanol is UV transparent, it is detectable through the baseline disturbance of the UV detector due to the change in refractive index. Sudan III and Sudan IV are widely used as micelle markers since they are highly lipophilic and totally incorporated into micelle. Timepidium bromide, Yellow OB, and Orange OT are also useful as tracers of micelles.

Note that eqn [3] was derived for the retention characteristics of neutral compounds. Hence, relationships between the migration time or mobility and retention factor will be more complicated when the

solute has an electrophoretic mobility; that is, the migration time of the ionic solute includes a portion ascribed to the migration of the micelle when the solute is incorporated into the micelle and also another portion ascribed to the electrophoresis of the solute itself.

### Resolution

The resolution ( $R_s$ ) in MEKC is given by eqn [7]

$$R_s = \frac{\sqrt{N}}{4} \cdot \left( \frac{\alpha - 1}{\alpha} \right) \cdot \left( \frac{k_2}{1 + k_2} \right) \cdot \left( \frac{1 - (t_0/t_{mc})}{1 + (t_0/t_{mc}) \cdot k_1} \right) \quad [7]$$

where  $N$  is the theoretical plate number,  $\alpha$  is the separation factor equal to  $k_2/k_1$ , and  $k_1$  and  $k_2$  are the retention factors of two closely eluting analytes, 1 and 2, respectively. The resolution increases in proportion to the square root of the plate number. The higher the applied voltage, the higher the plate number, unless the conditions are such that the applied voltage generates excessive Joule heating. The average plate numbers for most analytes are usually in the range of 100 000–200 000. If the plate number is considerably lower, analytes are likely to be adsorbed on the capillary wall. In such cases, experimental conditions must be optimized to produce more efficient separations. Cleaning of the capillary is a possible procedure, as is changing the pH of the run buffer. Hydrophobic analytes, or those having longer migration times, typically yield high theoretical plate numbers because the micelle has a smaller diffusion coefficient. This is explained by assuming the major band broadening is due to the longitudinal diffusion as in CZE. The plate number does not depend significantly on the capillary length. With short capillaries, however, the amount of sample volume injected must be minimized to avoid zone broadening.

The separation factor,  $\alpha$ , is the most important and effective term for maximizing the resolution. The separation factor reveals the relative difference of the distribution coefficient between the two analytes and can be manipulated by chemical means. Since the distribution coefficient is a characteristic of a given separation system, the selectivity can be manipulated by changing either the type of micelle or by modifying the aqueous phase.

The optimum value of the retention factor,  $k_{opt}$ , for maximum  $R_s$  can be calculated by differentiating the following equation, provided  $N$  is independent of  $k$ :

$$f(k) = \left( \frac{k_2}{1 + k_2} \right) \cdot \left( \frac{1 - (t_0/t_{mc})}{1 + (t_0/t_{mc}) \cdot k_1} \right) \quad [8]$$

Then,

$$k_{opt} = \sqrt{\frac{t_{mc}}{t_0}} \quad [9]$$

We can find that  $k_{opt}$  is a function of  $t_{mc}/t_0$ . Under neutral conditions, the optimum value is  $\sim 2$  for SDS micelles as the PS. For practical use, the range of  $k$  recommended is between 1 and 5, or at maximum between 0.5 and 10. Unlike conventional chromatography, in MEKC the micelles as the PS migrate with the bulk liquid due to the EOF, in addition to the electrophoretic migration. This migration of the micelle through the EOF does not affect the separation at all. However, the distance of the migration of the micelle cannot be used for the separation. Since the time available for the solute to interact with the moving micelle depends on its  $k$ , the column availability depends on  $k$  as shown by the last term of the right-hand side of eqn [7] or [8].

### Using Modifiers in MEKC

MEKC is usually performed with a BGE that consists of just a buffer and a surfactant. Other substances may be added to the BGE to alter the selectivity. Modifiers may affect the charge on the micelle or the solute and change the distribution of the solute between the micelles and the surrounding aqueous phase by interacting with the solute. The following categories of additives are applicable in MEKC: CDs, ion-pair reagents, organic solvents, and others.

#### Cyclodextrins

CDs are oligosaccharides with characteristic toroidal molecular shapes. Their outside surfaces are hydrophilic, while their cavities are hydrophobic. CDs tend to include molecules, which fit their cavities by hydrophobic interaction. The most widely used CDs consist of six ( $\alpha$ -CD), seven ( $\beta$ -CD), or eight ( $\gamma$ -CD) glucopyranose units. The size of the cavity differs significantly among the  $\alpha$ -,  $\beta$ -, and  $\gamma$ -CDs. Selectivity results from the inclusion of a portion of a hydrophobic solute into the cavity. The use of CDs is especially effective for the separation of aromatic isomers and aromatic enantiomers that have the chiral center close to the aromatic ring. Many CD derivatives have been developed for increased solubility in water as well as for modifying the cavity shape that provides different selectivities from underivatized CDs and are commercially available.

In CD-modified MEKC (CD-MEKC), separation is achieved because of differences in the distribution of the solute among the micelle, CD, and the aqueous phase. The analyte molecule included by CD migrates at the same velocity as the EOF because

CD electrophoretically behaves as the bulk aqueous phase. The neutral analyte molecule migrates at the same velocity as the EOF, whether included with CD or free from CD. On the other hand, the analyte migrates at a different velocity from that of the EOF when it is incorporated into the ionic micelle. Therefore, the addition of CD reduces the apparent distribution coefficient or  $k$  and enables the separation of highly hydrophobic analytes, which otherwise would be almost totally incorporated into the micelle. The higher the concentration of CD, the smaller the distribution coefficient. In CD-MEKC, therefore, the retention factor can be manipulated by varying either the concentrations of the micelle or CD. Enhancement of the separation selectivity of a group of polycyclic aromatic hydrocarbons (PAHs) using CD-MEKC using mixed CDs is shown in Figure 4.

### Ion-Pair Reagents

Ion-pair reagents are also very useful for selectivity enhancement of both ionic and nonionic analytes in MEKC. For example, when a tetraalkylammonium salt is added to an SDS micellar solution, the migration times of anionic analytes increase with an increase in the concentration of the ammonium salt

**Figure 4** Separation of 20 PAHs using mixed CD-MEKC. Conditions: Capillary, 65 cm  $\times$  50  $\mu$ m inner diameter (50 cm length to the detector); injection by pressure, 0.02 min at 20 mbar, the concentration of each PAH in the mixture was 0.1  $\mu$ g/ $\mu$ l; UV detection at 230 nm; separation solution, 0.042 mol l<sup>-1</sup>  $\beta$ -CD, 0.026  $\gamma$ -CD, 2.5 mol l<sup>-1</sup> urea, and 0.100 mol l<sup>-1</sup> SDS in 0.140 mol l<sup>-1</sup> borate buffer (pH 9); applied voltage, 15 kV. Solute identification: 1, acenaphthene; 2, acenaphthylene; 3, naphthalene; 4, benzo[*g,h,i*]perylene; 5, fluorene; 6, phenanthrene; 7, pyrene; 8, chrysene; 9, perylene; 10, anthracene; 11, benzo[*e*]pyrene; 12, benzo[*a*]pyrene; 13, benzo[*a*]anthracene; 14, fluoranthene; 15, dibenzo[*a,h*]pyrene; 16, benzo[*k*]fluoranthene; 17, triphenylene; 18, benzo[*j*]fluoranthene; 19, benzo[*b*]fluoranthene; 20, indeno[1,2,3-*cd*]pyren. (Reprinted with permission from Jiménez B, Patterson DG, Grainger J, *et al.* (1997) *Journal of Chromatography A* 792: 411–418. © Elsevier.)

because the ammonium ion interacts with the anionic analyte to form a paired ion. Hence, the electrostatic repulsion between the anionic SDS micelle and the anionic analytes is reduced. On the other hand, a cationic analyte competes with the ammonium ion in interacting with the anionic SDS micelle, and so the migration times of cationic analytes decrease with an increase in the ammonium salt concentration. The effect of the ion-pair reagent on selectivity depends strongly on the structure of the reagent, e.g., the length of the alkyl chain.

### Organic Solvents

Organic solvents miscible with water are widely used as mobile phase modifiers in reversed phase high-performance liquid chromatography (RPLC). Organic solvents may also contribute to the enhancement of resolution or alteration of selectivity in MEKC. However, it should be noted that a high concentration of the organic solvent might break down the micellar structure. In general, the maximum content of the organic solvent is 20–30%. Methanol, 2-propanol, and acetonitrile are widely used as organic solvents in MEKC. The addition of organic solvents usually reduces the EOF and, hence, expands the migration time window. The retention factor is also reduced because the solubility of the analyte into the aqueous phase increases.

### Other Additives

A high concentration of urea is known to increase the solubility of the hydrophobic compounds in water. Urea also breaks down hydrogen-bond formation in the aqueous phase. In MEKC, urea slightly reduces the electroosmotic velocity and considerably increases the electrophoretic velocity of the micelle, resulting in an expanded migration time window. The addition of urea is also effective in improving peak shapes, especially in the separation of amino acid derivatives. The selectivity is not remarkably changed by the addition of urea, but minor changes are noticeable, especially for the separation of closely related analytes.

Another approach for changing selectivity in MEKC is the use of metal ions. In particular, the MEKC separation of oligonucleotides is improved by the addition of Mg(II), Cu(II), and Zn(II) ions. Metal ions are electrostatically attracted to the surface of a negatively charged micelle where they can be selectively complexed with analytes. Separation is due to differences in the distribution of solutes between the buffer and the metal-micelle surfaces. Retention is proportional to the complexation constant

of the oligonucleotide and the metal–micelle surface. Using different metal ions can change the selectivity.

## Improving Detection Sensitivity

The most widely used detector in MEKC, which is common to other CE modes, is an ultraviolet (UV) photometric detector because many solutes have absorb UV, and the UV detector is easily set up and is cost efficient. One of the drawbacks of UV detection in MEKC is the low concentration sensitivity resulting from a short optical path length, equal to the capillary diameter, and the small injection volumes needed to maintain high efficiency. This limits the applicability of MEKC to trace analysis. Thus, method development is indispensable for reducing the limit of detection (LOD) or increasing the concentration sensitivity. There are different approaches that have been reported for improving the concentration sensitivity in MEKC. These investigations involve the use of highly sensitive detection methods, the installation of capillaries equipped with extended detection path lengths, and offline, and online sample preconcentration methods.

The frequently used highly sensitive detection method in MEKC is laser-induced fluorescence (LIF). LODs for this detection mode are at least an order of magnitude lower than that for UV detection. However, in an ordinary laboratory these detectors may not be affordable and UV detection is widely used as previously mentioned. From Beer's law, the absorbance is proportional to the path length, which is equal to the inner diameter of the capillary. Sensitivity can thus be enhanced through the use of larger inner diameter capillaries. However, this is not a good approach because large-diameter capillaries produce high currents, which cause Joule heating. The separation efficiency deteriorates dramatically when the capillary inner diameter is increased much above 100  $\mu\text{m}$ . Because of problems with large inner diameter capillaries, most approaches to improving the sensitivity have been directed toward extending the path length without increasing the inner diameter of the entire capillary. Bubble cell, Z-shaped cell, and multireflection cell detector configurations have been introduced, which have afforded from twofold to more than 10-fold enhancements in detector response. As with HPLC, a successful MEKC analysis would often rely on dedicated offline sample preparation methods (e.g., liquid–liquid and/or solid-phase extraction). Sample preparation methods usually increase the concentration of the analyte before injection into the capillary. However, these methods require somewhat complex or expensive hardware, with limited applicability, or are time consuming.

On the other hand, online sample preconcentration methods based on electrokinetic focusing of large sample volumes represent one of the most facile ways of sensitivity enhancement in MEKC since the preconcentration step is performed within the same capillary used for separation. Two of the most widely used techniques are sample stacking and sweeping. In general, the application of online preconcentration techniques in MEKC is dictated by the specific properties of the analyte and the sample matrix conditions. Thereafter, a variety of online sample concentration techniques have been reported in CZE. They are field-enhanced sample stacking, large-volume sample stacking, transient-isotachopheresis (ITP), pH-mediated stacking, and dynamic pH junction.

## Sample Stacking

The sample stacking technique was first introduced for ionic analytes in CZE. The basic model of sample stacking is illustrated in **Figure 5**. In CZE (**Figure 5A**), the sample is dissolved in a solution that has a lower conductivity than that of the BGE and injected as a longer plug than in normal injection. When a separation voltage is applied, the electric field strength experienced in the sample zone is higher than in the rest of the capillary. The sample ions in the sample zone will move quickly and then slow down when they reach the BGE zone because they experience a lower electric field strength. Consequently, the ions are focused at the boundary of the two zones. It should be noted that the EOF is assumed to be zero in **Figure 5A**. However, this technique cannot be applied to neutral analytes because neutral analytes have no electrophoretic mobility.

In MEKC (**Figure 5B**), to give effective electrophoretic mobilities to neutral analytes, charged PSs (e.g., anionic SDS micelles) are employed. The sample solution is prepared by dissolving the neutral analytes in a low-conductivity solution and injected into the capillary, which has been previously conditioned with an anionic SDS micellar BGE at neutral pH. The neutral analytes in the sample solution can be quickly carried to the boundary between the BGE and sample solution by the fast migrating anionic micelle entering the sample solution from the cathodic end. Since the electric field strength in the BGE zone is low, the velocity of the micelles is retarded, and the analytes are focused at the boundary between the BGE and the anodic end of the sample solution zone. Note that the neutral analytes are brought to the detector by the EOF since the magnitude of the EOF is greater than the electrophoretic velocity of the micelle.

**Figure 5** Schematic diagram of the principle of sample stacking in CZE (A) and MEKC (B).

However, a dispersive effect brought by the mismatch of local EOF velocities between the high and low electric field zones limits the injection length. To solve this problem, the stacking with reverse migrating micelles (SRMM) technique was developed. SRMM employs an acidic micellar BGE to reduce the EOF. Under this condition, the electrophoretic velocity of SDS micelles is higher than that of the EOF. Samples prepared in purified water or in low conductivity matrix are injected for a much longer time compared to the normal injection after conditioning the capillary with micellar BGE. Sample solutions are introduced at the cathodic end of the capillary, and then the separation voltage is applied with negative polarity at the injection end. Since the negative polarity is applied at the inlet, the sample matrix was slowly pushed out of the capillary by the weak EOF.

### Sweeping

The sweeping technique is defined as a phenomenon where analytes are picked up and concentrated by the micelle, which penetrates the sample zone devoid of micelle. It is independent of the EOF and effective for both charged and uncharged solutes.

The principle of sweeping under the acidic condition is schematically shown in Figure 6. In step A, test analytes prepared in a matrix, with conductivity similar to that of BGE but devoid of PSs, are pressure-injected into the capillary at the cathodic end. In step

B, once the separation voltage is applied at the negative polarity with the BGE in the inlet vial, the anionic PS will enter the capillary and sweep the analytes. In step C, the analytes are completely swept by the PS and followed by MEKC separation in the reverse migration mode. Under the optimized condition, ~5000-fold enhancements in detection sensitivity were obtained in terms of peak heights by sweeping.

Cation- and anion-selective exhaustive injection sweeping (CSEI-sweep and ASEI-sweep) techniques are also available in MEKC. CSEI-sweep and ASEI-sweep are combinations of two online preconcentration techniques, sample stacking with electrokinetic injection and sweeping, that can provide more than 100,000-fold enhancements in detection sensitivity. An electropherograms of tap water analysis by CSEI-sweep-MEKC is illustrated in Figure 7. The results of this study suggest that CSEI-sweep-MEKC can be used for the analysis of quaternary ammonium herbicides in drinking water.

### MEKC Hyphenation Technique with Mass Spectrometry

The use of mass spectrometry (MS) as a detection method in CE as well as EKC offers several advantages over the UV detection method. Analytes having no strong UV absorption are detected with a high sensitivity by MS detection. Furthermore, MS provides important information not only about the

**Figure 6** Schematic diagram of the principle of sweeping under acidic conditions.

**Figure 7** Electropherogram of tap water spiked with quaternary ammonium herbicides analyzed using CSEI-sweep-MEKC. Non-micellar BGE, 100 mmol l<sup>-1</sup> phosphate buffer (pH 2.5) containing 20% acetonitrile; micellar BGE, 80 mmol l<sup>-1</sup> SDS in 50 mmol l<sup>-1</sup> phosphate buffer (pH 2.5) containing 20% acetonitrile; high conductivity buffer (HCB), 200 mmol l<sup>-1</sup> phosphate buffer (pH 2.5); conditioning solution before injection, nonmicellar BGE; sample concentration, 10 µg l<sup>-1</sup> paraquat (PQ), diquat (DQ), and ethylviologen (EV, internal standard), 50 µg l<sup>-1</sup> difenzoquat (DF). Injection scheme: hydrodynamic injection of HCB for 200 s (5 kPa), hydrodynamic injection of water for 6 s (5 kPa), electrokinetic injection of sample for 400 s (+22 kV); separation voltage, -22 kV with the micellar BGE at both ends of the capillary. s.p., system peak. (Reprinted with permission from Núñez O, Kim JB, Moyano E, Galceran MT, and Terabe S (2002) *Journal of Chromatography A* 961: 65–75. © Elsevier.)

molecular mass but also about the structure of the analytes. The most important issue in CE-MS may be the development of interfaces between CE and MS. MS has been successfully coupled to CE with various

interfaces. An electrospray ionization (ESI) interface is widely employed in CE-MS systems. However, the major drawback in MEKC-MS with an ESI interface is that the introduction of a nonvolatile PS into the

interface reduces the ionization efficiency and contaminates the interface. To solve this problem, the use of the partial filling (PF) technique has been developed. In the PF technique, the micellar solution is filled only in a part of the capillary, and the analyte will interact with the micelle when passing through the micellar zone. In PF-MEKC, the applied voltage for the MEKC run will be cut off before the micellar zone reaches the end of the capillary or the interface to the mass spectrometer, so that the micelle is not introduced into the mass spectrometer.

As an alternate ionization method to ESI, the atmospheric pressure chemical ionization (APCI) has been applied to the MEKC-MS system. In MEKC-APCI-MS, an SDS micellar solution can be introduced directly into the interface without a severe decrease in MS intensity. For highly sensitive analysis of environmental pollutants, an application study of sweeping to MEKC hyphenated with MS using an APCI interface has been reported.

## Introduction

Miniaturized total analytical systems ( $\mu$ TAS) for chemical measurement have become important because they are reported to offer significant advantages over analytical systems of more conventional scale. These advantages are reported to include reduced reagent consumption and waste production, increased speed of analysis hence improved rates of sample throughput, and facilitating analysis in the field. There are other reported advantages with such systems, including the need for only very small volumes of sample (important where sample volume is limited) and disposability (particularly important for DNA replication work and clinical applications).

A common alternative name for  $\mu$ TAS is Lab-on-a-Chip. This article will describe typical  $\mu$ TAS, explain how such devices are made, and finally discuss a range of applications.

## Total Analytical Systems and $\mu$ TAS

Chemical analysis does not consist solely of a physical measurement process providing a numerical value, e.g., concentration of pesticide, or identification, e.g., the unknown substance was 3,4-dinitrophenol. The actual measurement is one small part of a far more complex process commencing with sample collection and concluding with data interpretation. The complete analytical process can include filtration, pH adjustment, dilution, reagent addition, calibration, in addition to making the physical measurement and data processing. It has long been recognized that automating all these steps would

interface reduces the ionization efficiency and contaminates the interface. To solve this problem, the use of the partial filling (PF) technique has been developed. In the PF technique, the micellar solution is filled only in a part of the capillary, and the analyte will interact with the micelle when passing through the micellar zone. In PF-MEKC, the applied voltage for the MEKC run will be cut off before the micellar zone reaches the end of the capillary or the interface to the mass spectrometer, so that the micelle is not introduced into the mass spectrometer.

As an alternate ionization method to ESI, the atmospheric pressure chemical ionization (APCI) has been applied to the MEKC-MS system. In MEKC-APCI-MS, an SDS micellar solution can be introduced directly into the interface without a severe decrease in MS intensity. For highly sensitive analysis of environmental pollutants, an application study of sweeping to MEKC hyphenated with MS using an APCI interface has been reported.

## Introduction

Miniaturized total analytical systems ( $\mu$ TAS) for chemical measurement have become important because they are reported to offer significant advantages over analytical systems of more conventional scale. These advantages are reported to include reduced reagent consumption and waste production, increased speed of analysis hence improved rates of sample throughput, and facilitating analysis in the field. There are other reported advantages with such systems, including the need for only very small volumes of sample (important where sample volume is limited) and disposability (particularly important for DNA replication work and clinical applications).

A common alternative name for  $\mu$ TAS is Lab-on-a-Chip. This article will describe typical  $\mu$ TAS, explain how such devices are made, and finally discuss a range of applications.

## Total Analytical Systems and $\mu$ TAS

Chemical analysis does not consist solely of a physical measurement process providing a numerical value, e.g., concentration of pesticide, or identification, e.g., the unknown substance was 3,4-dinitrophenol. The actual measurement is one small part of a far more complex process commencing with sample collection and concluding with data interpretation. The complete analytical process can include filtration, pH adjustment, dilution, reagent addition, calibration, in addition to making the physical measurement and data processing. It has long been recognized that automating all these steps would

make analysis quicker and less expensive, and total analytical systems (TAS) have been developed to do just that. TAS are instruments that can process a sample, ideally from the point of collection to the production of the analytical report, and include all the sample preparation, instrument calibration, and measurement. Unfortunately, the devices are usually large and expensive to operate, i.e., high consumption of reagents and sample, production of large amounts of waste, and are mechanically complex.

It has long been recognized that reducing the scale of the chemistry (this is not the same as making the instrument smaller) reduces the reagent consumption, increases sample throughput, and shortens reaction times. These advantages, along with developments in fabrication techniques from the electronics industry led to the reality of  $\mu$ TAS; planar systems providing fluidic manipulation and measurement on a small scale (typically in a network of channels of 100  $\mu$ m width or less). The idea of miniaturized instruments was first reported in the 1950s when Terry and co-workers reported the fabrication of a gas chromatograph on a silicon wafer. This had an integral detector and was perhaps the first reported  $\mu$ TAS. After that, while some interest remained, little progress was made until the 1980s when Manz started to develop the idea and interest was rekindled. Such was the potential importance; interest within the scientific community grew very rapidly. During the following decade interest continued to grow and diversify from simple fluidic manipulations and electrophoretic separations to chemical synthesis and reaction chemistry. Devices were often referred to as 'chips' and the term Lab-on-a-Chip was coined. In this article, the focus will be on Lab-on-a-Chip devices for analysis rather than chemical microreactors for synthetic applications.

## Fabrication of Devices

The majority of the fabrication techniques used to manufacture  $\mu$ TAS or Lab-on-a-Chip devices has been developed from the microelectronics industry. A wide range of techniques are available and a comprehensive treatment is beyond the scope of this article. A typical device consists of two layers or plates: the base plate and the cover plate. The channel network is formed in the base plate by a suitable micromachining method. The network is closed by the cover plate, which also contains the fluid transfer connections or the reservoirs and possibly the electrodes. The two plates are either pressed firmly together or irreversibly bonded to form liquid tight seals. A diagram of a typical device can be seen in Figure 1. Devices with multiple channel layers are

**Figure 1** Diagram showing a typical chip. The channel design consists of two intersecting channels with reservoirs at the ends of the channel.

being developed, where the different channel layers are connected via microflow control valves.

## Materials Used

There are a number of materials used for the fabrication of  $\mu$ TAS devices. Perhaps the most common is glass due to its low cost, ease of machining, and suitability for electrophoresis and electroosmotic flow (EOF) applications without requiring surface modifications. It is also chemically inert to most reagents (apart from hydrofluoric acid and concentrated alkali). Silicon is also a valuable material that has similar chemical inertness and can easily be machined by chemical etching. While it is more expensive, it can be easily chemically etched to yield far higher aspect ratios than are possible with glass. Silicon is not suitable for electrophoresis or EOF applications without surface pretreatment. Devices fabricated from polymers such as polymethylmethacrylate (PMMA) and polydimethylsiloxane (PDMS) are also frequently used due to the low cost of the material (especially important for disposable devices) and the ease of fabrication. Perhaps one drawback with polymers is their incompatibility with solvents. They are suited to electrophoretic applications but frequently require surface modification to support EOF. Occasionally, metals are used; however, these are far more frequently encountered in chemical microreactors.

## Micromachining Methods

The choice of machining method is somewhat material dependant, however, wet chemical etching in conjunction with photolithography is a highly

versatile method suitable for both glass and silicon, and can be readily employed in most laboratories. Molding and hot embossing are machining methods reserved for polymers and permit the replication of hundreds of devices from a single master; this can be of significant importance where disposable devices are required. More specialist fabrication techniques include lamination, laser ablation, and dry etching methods using plasmas and reactive ion beams. While all the above methods require some degree of specialist facilities, the latter methods tend to be more specialist and will not be discussed further.

### Wet Chemical Etching and Photolithography

This machining technique (shown schematically in Figure 2) involves etching a channel network into a glass or silicon substrate, the pattern of the channel network is defined by selectively removing areas of a resist layer on the surface. Glass or silicon is first coated with a layer of photoresist, typically  $0.1\text{--}2\text{ }\mu\text{m}$  thick by spin coating. (It should be noted that far thicker layers can be obtained if specialist photoresists are used.) Glass substrates are frequently coated in a thin layer ( $>100\text{ }\text{\AA}$ ) of chromium and

gold prior to the application of the photo resist. The pattern of the required channel network is produced as a photo mask, which is placed between the light sensitive layer and a source of radiation, usually an ultraviolet (UV) source. In a similar way to a photograph, upon exposure, the pattern is transferred to the layer of photoresist. It is also possible to use a direct writing laser to pattern the resist. The exposed resist can be removed using developer and the substrate surface exposed beneath. When the glass is exposed to certain chemicals (etchants), channels are etched into the glass. The etch depth is time dependent. The resultant channel profile will be dependant upon whether the etch process is isotropic or anisotropic.

**Isotropic versus anisotropic etch** Glass is always etched isotropically because the etchant etches all exposed surfaces at the same rate. This is independent of the etchant used and arises because glass does not have different planes. Depending on etchant, silicon is either etched isotropically or anisotropically. Anisotropic etching occurs where material on one plane is removed at a greater rate than material on a different plane. The difference is most apparent in terms of channel shape and aspect ratio. Isotropic

**Figure 2** A schematic representation of device fabrication by photolithography and wet chemical etching of a glass substrate.

**Table 1** The influence of some common etchants

<i>Etchant</i>	<i>Substrate</i>	<i>Effect</i>
HF/HNO <sub>3</sub> <sup>a</sup>	Glass	Isotropic etch
HF/HNO <sub>3</sub> <sup>a</sup>	Silicon	Anisotropic etch
KOH, NaOH, NH <sub>4</sub> OH	Glass	Little effect, isotropic etch if any
KOH, NaOH, NH <sub>4</sub> OH	Silicon	Anisotropic etch

<sup>a</sup>Acetic acid is the preferred diluent since it better maintains the oxidizing properties of HNO<sub>3</sub>.

**Figure 3** The channel profiles for a channel etched isotropically and anisotropically into a silicon substrate. The same mask line width was used for both.

etches form rounded channels with low aspect ratio, e.g., a channel produced in glass by acid etching will have a width equal to the original mask line width plus twice the depth. A channel anisotropically etched into silicon produces deep channels with near vertical sides and high aspect ratios. The influences of etchant on the different materials can be seen in Table 1 and the shapes of channels produced by isotropic and anisotropic etching can be seen in Figure 3.

### Molding and Hot Embossing

These methods of micromachining are ideally suited to polymeric material. Molding is frequently used with polymeric resins such as PDMS that are initially liquid and become solid on heating. A master is first fabricated from silicon, glass, or metal such that the channel network is formed as a series of ridges on the surface. When the polymeric resin is allowed to cure over this, a channel network is formed in the mating face of the polymer. Hot embossing is used to form a channel in a rigid polymer such as PMMA, where pressing a pattern into the surface of the polymer forms the channel network.

## Fluidic Movement within the Device

The method of inducing bulk flow of fluid within the device can take two general forms; pressure driven flow and electroosmotically induced flow. Both methods have advantages and disadvantages and are somewhat dependent on the construction material. Although there are many methods of inducing pressure driven flow, the ultimate flow characteristics are similar.

### Pressure-Driven Flow

Over the years, there have been many attempts to develop microfabricated pumps with varying degrees of success. Such devices were based on piezoelectric wafers, etc. Their success was variable and while efforts continue, there are many limitations. Syringe pumps can deliver flow rates typically between 0.1 and 1  $\mu\text{L min}^{-1}$  and are frequently used with  $\mu\text{TAS}$ . The flow is virtually pulse free and, due to the low flow rates used, the problem of refilling the syringe is less significant. An alternative is to use microperistaltic pumps; however, the pulsation can be very high. Pressure-driven flow is not influenced in any way by the material of construction. In all cases, the flow profile is parabolic and can lead to diffusion or turbulent flow, a problem not encountered with EOF. Volume flow rates through the channel are directly proportional to the applied pressure and the cross-sectional area of the channel, but inversely proportional to the length of the channel and the viscosity of the buffer. It is clear that higher pressures will be required to achieve the same volume flow rate through long channels with small cross-sectional area compared to short channels of large cross-sectional area. This can lead to restrictions in channel dimensions (both length and cross-section) when pressure-driven flow is used.

### Electroosmotic Flow

This approach to fluidic propulsion does not rely on mechanical pumping; rather, it is a surface-induced phenomenon. It requires an electrical insulator as the channel material and the ability of the surface to form a double layer. This tends to limit the applicability to glass, surface modified silicon, and surface modifier polymer. EOF is best described by considering the situation occurring in a buffer-filled channel in a glass substrate.

Consider a channel network fabricated in a glass substrate and filled with an aqueous buffer of pH10. The glass surface is covered with a layer of silanol (Si-OH) groups and at this pH; many are dissociated (Si-O<sup>-</sup>). A layer of cations develops near to this surface since they are attracted by the negative

**Figure 4** The formation of the electrical double layer and the flow profile resulting from the application of an applied voltage along the channel.

charge on the surface. In the absence of an applied voltage, nothing else happens. When a voltage is applied along the channel, it causes the cations to migrate toward the negative electrode. This process results in bulk fluid movement (EOF) toward the negative electrode. Unlike pressure-driven flow, the flow profile is laminar, leading to very little turbulence. This process can be seen schematically in **Figure 4**. The applied electric field is usually delivered from electrodes located in the fluid reservoirs. The magnitude of the flow (EOF<sub>m</sub>) is related to the charge on the surface of the channel (often referred to as the Zeta potential ( $\zeta$ )), the viscosity of the buffer ( $\eta$ ), and the dielectric constant of the buffer ( $\epsilon$ ):

$$\text{EOF}_m = \epsilon \zeta / \eta$$

Due to the ionization of the silanol groups, the Zeta potential is strongly influenced by the pH of the buffer; the pH tends to have the greatest influence on flow and therefore needs to be carefully controlled. EOF also increases with increasing field strength, i.e., applied voltage per centimeter. The length and cross-sectional area has less influence on flow rate when EOF is used to pump fluids through channels; hence, this can have significant advantages in certain designs of device.

## Analytical Applications

There have been a vast number of publications in the general area of Lab-on-a-Chip research; however, most devices reported are not true  $\mu$ TAS. Earlier,  $\mu$ TAS were defined as devices that performed the total analytical process, from sample preparation to analysis. Many systems reported perform only some of these functions; frequently the sample preparation aspect is omitted. It remains common practice to use

the term  $\mu$ TAS for systems that do not meet all the steps in the analytical process but are miniaturized devices performing some of the analytical steps.

In the simplest mode of operation,  $\mu$ TAS can be used as a miniature flow injection system either to carry samples from the point of injection to the point of detection with the possible addition of reagents into the stream. Fluid manipulation can be achieved by pressure pumping, EOF, or electrophoresis (though not resulting in bulk fluid movement, it can be very effective for moving ionized species through the bulk). One early example of an application of  $\mu$ TAS as a flow injection system was the determination of orthophosphate by the molybdenum blue reaction. Here a water sample was introduced into a reagent stream by EOF where the colored molybdenum blue complex was formed and the absorbance measured further along the channel. Such systems take advantage of the low reagent consumption and ease of sample manipulation on small planar structures.

The channel sizes typical of  $\mu$ TAS make them ideal for manipulating and analyzing cells. Cells can be transported through the channels by pressure pumping on EOF, then lysed prior to analysis of contents.  $\mu$ TAS has the unique advantage that since the volumes are small, dilution of the cell contents does not occur to any significant extent during the lysing process. This is useful for all cells and microorganisms, but can offer particular advantages when applied to other microorganisms of a more harmful nature.

## Extraction, Preconcentration, and Matrix Removal

The incorporation of extraction methodologies into  $\mu$ TAS can allow unprepared samples to be analyzed. The simplest step is to fabricate filtration units, typically consisting of small sections of shallow channels or porous plugs at the start of analytical channels. These serve to remove particulates from the sample; therefore, unfiltered samples can be introduced with no detrimental effect on the performance of the system. Often, samples can be particulate free but require extraction of the analyte from the matrix, either for preconcentration or for matrix removal. There have been several reports of liquid-liquid extraction being fabricated into  $\mu$ TAS. Usually, two immiscible streams (the sample and the extracting fluid) are pumped down a single channel, where the extraction takes place at the fluid interface. The streams are then separated by splitting the channel. Mixing of the streams does not occur since the flow is laminar; this, however, results in a less efficient extraction system since it is diffusion limited. An

alternative strategy is to incorporate solid phase extraction material into the channel, either as a solid or wall coated to preconcentrate and/or remove interfering species from the sample.

### Separation

This aspect of  $\mu$ TAS is considered by many to be one of the most important aspects permitting separation of complex analytical samples into separate components, eliminating the need for selective detection. While many different strategies have been reported, the two most common are based on electrophoresis and chromatography. In both cases, small volumes of sample are injected into a channel and the various components in the sample are separated on the basis of their electrophoretic mobility or their interaction with a stationary phase. The size of the sample plug will be vital to the reproducibility of the separation, both in terms of resolution and quantification.

### Chromatography

The separation is achieved by pumping a small plug of analyte through a channel either packed, or wall coated with stationary phase. Packed channels yield high back pressures, which is a significant problem with pressure pumped systems. EOF overcomes this problem to a large extent, and the effect observed is comparable to that occurring in capillary electrochromatography. While wall coated stationary phase does not suffer from the back pressure problem, it does lack sample capacity and overloading is likely. This can only be addressed by ensuring that the minimum sample volume is introduced. An alternative to these strategies is to fabricate monoliths in the channel, e.g., by specialist etching of silicon and subsequent chemical modification, to effectively increase the surface area of the stationary phase without filling the channel with small particles. There is increasing use being made of separations based on chromatography particularly where preconcentration and separation can be achieved in a single channel. The first part of the packing can be used to preconcentrate the analyte prior to elution down the remainder of the column with an appropriate solvent.

### Electrophoresis Separations

Electrophoresis separations rely on differing electrophoretic mobilities of the analytes, so clearly this separation approach is only valid for separating charged analytes. The most popular type of separation is based on straightforward differences in migration mobilities of the analytes, i.e., as in capillary

electrophoresis. Where a voltage is applied along the length of a channel, the ions migrate under the influence of that charge. The electrophoretic velocity ( $v$ ) of a given ion is related to the charge on the ion ( $q$ ), the solution viscosity ( $\eta$ ), the radius of the ion ( $r$ ), and the applied electric field ( $E$ ) by the equation below:

$$v = E(q/6\pi\eta)r$$

Since the electrophoretic mobilities (and hence the velocities) are dependent on the radius and charge of the ions, they will become spatially resolved along the channel if the mobilities of each species are sufficiently different, therefore reaching the detector at different times. Since the electrophoretic mobility of all uncharged materials is effectively zero, this approach cannot be used to separate uncharged species. While this approach has been used for many applications, perhaps its most important is its use in separating small biomolecules and fragments of DNA. Analysis of DNA can rapidly be performed on  $\mu$ TAS, offering advantages over other separation techniques of speed, minute sample volume, and disposability. The latter advantage is particularly important where contamination must be avoided.

Another frequently employed electrodriver separation process is isotachopheresis, again based upon differing rates of migration in an applied electric field, but unlike capillary electrophoresis methods employs a leading and tailing electrolyte. All separated species are contained between the two electrolyte bands, thus ensuring all the analytes reach the detector in a controlled period. This is somewhat less frequently used than capillary electrophoresis.

## Introduction

There are many different types of microbiological analyses available to the modern microbiologist. These are based on a wide variety of detection principles and range from direct to indirect, manual to automated, fast to slow, and total to specific. The choice of method will be largely affected by the specific application and the user's requirements in terms of determinant and sensitivity. In general, the methods can be used for a wide range of applications, e.g., food, pharmaceutical, water, environmental, clinical, etc. Microbiological methods can be used to enumerate 'total numbers' of bacteria, yeasts, and molds in test materials, 'indicator organisms' of fecal or other contamination, and pathogens that may cause food poisoning or even death. In addition, there are methods for identifying bacteria, yeasts, and molds isolated or enumerated by these techniques. Although a large number of methods are addressed, space limitations do not allow for sufficient descriptions to enable one to discuss most of those covered. For this purpose, the reader should consult one or more of the listed references for the method of choice that pertains to the use or application of the results. Finally, the methods addressed are primarily for chemoheterotrophic bacteria, commonly occurring yeasts and molds, and some viruses and protozoa that cause human gastroenteritis.

## Types of Methods

Methods for estimating microbial numbers can be divided into two groups: direct and indirect. Direct methods count cells directly, either by the ability of viable cells to grow and form colonies, or microscopically. Indirect methods measure a chemical constituent, enzyme, metabolite, or changes produced by organisms during growth. This measurement is converted into numbers by reference to a calibration graph. The 'true' numbers of organisms for the calibration graph are usually assessed by direct methods. Generally, direct methods are more sensitive and accurate than indirect methods and cultural methods

take longer to give a result than microscopic or indirect methods.

While not developed for the enumeration of microorganisms, a number of methods have emerged that can be used to type, characterize, or 'fingerprint' microbial species or strains. These techniques are very valuable in studying the epidemiology of pathogens and in profiling microorganisms that occupy common environmental niches. The bioassay methods are important in assessing certain virulence properties among human and animal pathogens.

## Direct Methods

**Resuscitation and enrichment methods** Some bacteria and fungi that have been frozen, dried, sublethally heated, or exposed to chemical inhibitors may suffer sublethal damage and not replicate when placed on growth media, especially media that contain selective inhibitors. If these cells are not allowed to resuscitate, under-counts may result and, in the case of pathogens, a product may be declared pathogen-free when in fact it is not.

When food or environmental samples are believed to contain numbers of the organism of interest that are below the detection limit of a given viable enumeration method, nonselective enrichment methods may be used. This consists of the addition of, e.g., 25–50 g of sample to a general growth broth to allow the low number of cells to increase. Not only can this increase the original low number to a detectable level, it will allow environmentally stressed cells to resuscitate. Selective enrichments employ agents in the medium that favor a given species or group. For example, a general culture medium that contains 7.5% NaCl becomes selective for *Staphylococci*. Metabolically stressed cells should be allowed to resuscitate in a nonselective broth (e.g., 4–6 h in trypticase soy broth at refrigerator temperatures).

The most widely used colony count methods are further discussed below along with some parameters that affect colony results.

**The pour plate** The plate colony count isolates bacteria, yeasts, or molds in a quantitative manner. A range of dilutions, usually 10-fold of the sample, is prepared in a sterile diluent and 1 ml of each dilution is added to sterile Petri dishes, mixed with melted agar cooled to 45°C, and then allowed to solidify. The organisms present in the sample are fixed within the agar gel. Pour plates are then incubated for 2–5 days at 25–37°C, depending on the application,

during which time viable organisms replicate to form visible colonies. Individual colonies on a plate containing 15–150 colonies are counted and then the count per milliliter or per gram is calculated by multiplying the colony count by the appropriate dilution factor (Figure 1). One of the major disadvantages of the plate colony count is that it takes 2–5 days to give a result. The plate colony count is very sensitive because, in principle, any viable cell when placed in an appropriate medium and incubated at a suitable temperature will give rise to a colony. It is important to note that the plate colony count is subject to errors, and provides only an estimate of the ‘true’ numbers of organisms. These errors, which are mainly due to sampling and decrease with increasing bacterial numbers, are often in the range  $\pm 10\%$  to  $\pm 40\%$ . Automation of the plate colony count enables an operator to perform analyses more rapidly than by the manual method. However, for plate colony count methods, the length of time taken to give the result is mostly due to the incubation period required for colony formation. Automation of the preparation of the plate does little to decrease the overall time required for the technique. Some examples of colony count and related methods for various organisms are summarized in Table 1.

Savings in time and materials can be made by removing the need for the dilution series in the standard plate colony count. Various methods based on the Thompson plate loop method have been described. In the technique, two loops that retain 0.01 and 0.001 ml are dipped into the sample. A Petri dish is positioned under each loop and the loops are flushed with diluent, agar is then added, and the contents of the Petri dish are mixed. These machines can plate  $10^{-2}$  and  $10^{-3}$  dilutions from 300 samples per hour. The technique is suitable for enumerating bacteria in the range  $3000\text{--}300\,000\text{ ml}^{-1}$ . Manufacturers of one commercially available automated plate loop machine (PetriFoss) claim that the relationship with the reference method has a correlation coefficient of 0.99.

**Surface plating** Several methods are now in use that lead to the growth of all colonies on the surface of the culture medium – agar plate, dry film, hydrophobic grid membrane filter (HGMF), etc.

Sample preparations for the agar surface plate are the same as for pour plating except that smaller, e.g., 0.1 ml, volumes are used on plates. Plates are poured with the appropriate medium a day or two in advance of use so that the surface is dry. After 0.1 ml of serial dilutions is planted, they are spread over the entire plate surface with a sterile bent glass or plastic rod (‘hockey stick’). Surface plating is

**Figure 1** Colonies of microorganisms on agar plates after incubation: (A) close-up of bacteria; pour plate, plate count agar; (B) close-up of mold; surface plate, oxytetracycline glucose yeast extract agar; (C) *Salmonella* species; streak plate, xylose lysine decarboxylase agar.

**Table 1** Examples of some conventional colony count methods that may be used to enumerate microorganisms from a variety of samples

Organisms/groups	Culture media <sup>a</sup>	Incubation	Time for results
Anaerobic bacteria	AC agar or PCA	30–35°C	48–72 h
Aerobic sporeformers	PCA after heat shock	35°C	24–48 h
<i>Bacillus cereus</i>	MYP or KG agar	35°C	24 h
<i>Campylobacter jejuni</i>	CCDA-Preston blood-free medium; Campy-Cefex agar	42°C	18–48 h
<i>Clostridium perfringens</i>	SPS, SFP, or TSC agar	35°C	24 h
Coliforms	VRB agar	35°C	24–48 h
<i>Escherichia coli</i>	Petrifilm	35°C	24 h
<i>E. coli</i> O157:H7	Sorb. MacConkey agar	35°C	24 h
Enterobacteriaceae	VRB glucose agar	35°C	18–24 h
Enterococci	KF Strep, FGTC agar	35°C	24–48 h
Fungi (yeasts, molds)	DRBC, Sabouraud, or PCA + antibiotics	22–25°C	3–5 days
Lactic acid bacteria	MRS or KF Strep agar	35°C	48 h
<i>Listeria monocytogenes</i>	LPM or modified McBride agar	35°C	24–48 h
Psychrotrophs	PCA	5–7°C	10 days
Psychrophiles	PCA	< 12°C	3–5 days
Staphylococci	Baird-Parker agar	45°C	24 h
Thermophiles	PCA	55°C	24 h

<sup>a</sup>CCDA, *Campylobacter*-charcoal-differential agar; DRBC, Dichloran Rose Bengal Chloramphenicol; FGTC, fluorogenic gentamicin-thallos-carbonate agar; LPM, lithium-phenylethanol-moxalactam agar; PCA, plate count agar; SPS, sulfite-polymyxin-sulfadiazine; TSC, typtose-sulfite-cycloserine; VRB, violet red bile.

Many or most of these determinations can also be made by use of Petrifilm, HGMF, or SimPlate.

preferred to pour plating for the enumeration of psychrotrophs and psychrophiles. Also, it allows one to observe the size, texture, and pigmentation of all colonies if they are well isolated. Use of the spiral plater is an efficient way to prepare pour plates, and this device is described below.

The spiral plater method for enumerating organisms also avoids the use of a dilution series. By using a varying rate of sample application, it needs only one plate to obtain counts over a range that will require two or three plates in the standard plate colony count. The spiral plater deposits a known volume of sample on a rotating plate in an ever decreasing amount in the form of an Archimedes spiral. After incubation, different colony densities are apparent, closely packed, or confluent in the center to well isolated at the outside. A counting grid that relates the area of the plate examined to the volume of the sample is used to convert the count in a given area of the plate to the numbers of organisms per milliliter or per gram of sample. This can be done automatically in a few seconds by a laser colony counter or image analyzer. Using the spiral plater and laser colony counter, samples containing organisms in the range 500–300 000 ml<sup>-1</sup> can be analyzed in about one-third the preparation time of the standard plate colony count.

**Most probable number (MPN)** This is a widely used culture procedure that provides a statistical estimate of the MPN of viable organisms in a sample.

It is commonly used in the examination of waters and foods for coliforms and *Escherichia coli*. The three-tube method employs nine tubes to which three successive decimal dilutions of specimen are planted into three tubes each. The five-tube method is the same except that five tubes of each dilution are inoculated. After a suitable incubation, positive tubes of each dilution are recorded and used to arrive at the MPN by use of standard three- and five-tube tables.

**Dry films** The most widely used of these methods is Petrifilm<sup>TM</sup>, which consists of a particular culture medium semidried onto a plastic sheet covered with a see-through film. The Petrifilm APC contains triphenyltetrazolium chloride, which aids in viewing colonies. These Petrifilm ‘plates’ are inoculated with 1.0 ml of diluted specimen and then incubated at the appropriate temperature. Selective Petrifilm ‘plates’ are available for coliforms, *E. coli*, and fungi. These methods give results comparable to those obtained by pour or surface plating.

The SimPlate<sup>TM</sup> is a method that resembles a plating method in its setup but individual colonies are not enumerated. It can be viewed as an MPN method that uses special plates rather than tubes. The special plates contain 84 or 198 wells and a diluted sample is added to a single plate. Broth is then added and distributed evenly into the wells with excess medium being decanted. After incubation for 24 h, plates are exposed to ultraviolet light and the fluorescent wells are counted. Special MPN tables are used to

calculate numbers per gram or per milliliter in the original sample. Selective SimPlate media are available for coliforms and *E. coli*.

**Microscope slide methods** A specimen smear on a glass slide followed by simple or differential staining remains one of the fastest ways to determine numbers of bacteria or yeasts. A minimum number of cells of  $\sim 10^4 \text{ cm}^{-2}$  are needed. Both viable and nonviable cells may be enumerated and results can be obtained in  $\sim 5$  min. A number of slide counting devices exist with the Breed slide method being one of the most widely used. The Breed smear was one of the first methods to use microscopy for counting bacteria in milk and involved the preparation of milk films, staining with Methylene Blue, and then microscopic examination.

**Direct epifluorescent filter technique (DEFT)** The DEFT was originally developed as a rapid method for counting bacteria in raw milk and is now used for a range of food, water, pharmaceutical, and medical applications. The DEFT uses membrane filtration, fluorescent staining, and epifluorescence microscopy. Some products require treatment with an enzyme and surfactant to enable a sufficient amount to filter through a  $0.6 \mu\text{m}$  polycarbonate membrane filter. Microbial cells remain intact and are concentrated on the surface of the membrane. After staining with Acridine Orange [3,6-bis(dimethylamino)acridinium chloride], cells fluoresce orange-red under blue light. 4',6-diamidino-2-phenylindole is a DNA-specific stain that fluoresces blue or bluish-white when excited with light of 365 nm wavelength. With either dye, the cells are easily counted using an epifluorescence microscope. The DEFT count is rapid, taking 25 min to complete, is inexpensive, correlates well with the plate colony count ( $r > 0.9$ ), and is suitable for raw milks containing  $5 \times 10^3$  to  $10^8$  bacteria per milliliter.

One of the major disadvantages of the manual DEFT is operator fatigue associated with prolonged use of the microscope. This can be eliminated by the use of a semiautomated counting system based on an image analyzer. An instrument has been marketed (the Biocom Cobra) that automates fully the sample filtration, staining, rinsing, drying, and counting stages of DEFT. One operator can process  $\sim 96$  samples per hour and results are available in  $\sim 30$  min. Compared with the standard DEFT, miniaturization has led to substantial cost savings,  $\sim 80\%$ , on disposables.

One can determine viable cells by use of microcolony-DEFT. This is achieved by placing DEFT membranes (through which homogenates have been filtered) on the surface of an appropriate culture

medium and incubating for 3 h for Gram-negative bacteria and 6 h for Gram-positives to allow microcolonies to develop, which, after fluorescent staining, are then viewed with a microscope. As few as  $\sim 10$  cells can be detected within  $\sim 8$  h. Antibody (Ab)-DEFT for Gram-negative bacteria can be applied to specimens without enrichment and results can be obtained in  $< 1$  h with as few as  $16 \text{ CFU g}^{-1}$ . Ab-DEFT employs a fluorescein-labeled antibody to the organism of interest and results are determined by use of epifluorescence microscopy.

The Bactoscan instrument uses fluorescence microscopy for the automated counting of bacteria in milk. Milk somatic cells and casein micelles are dissolved chemically and then the bacteria are separated by continuous centrifugation in gradients formed with solutions of dextran and sucrose. The bacteria recovered from the gradient are incubated with protease, to remove residual protein, and then stained with Acridine Orange. For counting, the treated sample is applied as a thin film on the surface of a rotary disc and passed under a microscope objective. The fluorescent impulses in the microscope image are converted into electrical impulses and recorded. The instrument can analyze 80 samples per hour with an analysis time of 7 min.

**HGMF** The technique reduces the need for dilutions of the sample before enumeration, and hence reduces processing time, as well as giving better recovery than conventional filters, especially where high numbers of bacteria are involved. The HGMF has a square grid pattern printed in hydrophobic material, such as wax, on a conventional membrane filter. This divides the filter into a number of compartments, usually 2000–4000 depending on the size of the grids. The device functions as an MPN technique, eliminating size variations in colonies and preventing lateral spread. This greatly facilitates the automated counting of the colonies. Growth in a grid cell does not necessarily equal one colony in the plate colony count, since frequently a grid is inoculated with more than one organism. Coincidental inoculation is allowed for in calculating the count per milliliter or per gram of sample.

### Indirect Methods

There is a long list of methods that can be used to detect and/or enumerate microorganisms by measuring parts of cells or by substrate reactions, and the list continues to grow. Some of the most widely used are summarized in Table 2.

**Dye reductions** Dye reduction tests are based on the ability of bacterial enzymes, such as

**Table 2** Summary of some indirect methods for detecting or enumerating microorganisms or their products

Methods	Applications	Time for results	Sensitivity
ATP assay	Total viable cells	5 min	$\sim 10^3$ cells
DNA probes	Cells	1–2 days	1–5 cells
Colony hybridization	Viable bacterial cells	16–24 h	1–10 cells
Dot blot analysis	Viable bacterial cells	2–4 days	1 CFU g <sup>-1</sup>
ELISA	Enterotoxins, mycotoxins, Gram-negative bacteria	1 h for toxins; 20–36 h for cells	0.01–0.1 ng <i>Staph. enterotoxin</i> ; $\sim 5$ ppb for some mycotoxins
Impedance	Total viable bacteria	> 6 h	$10^5$ – $10^6$ cells
	Coliforms and yeasts	in 4 h	10
Immunodiffusion	Soluble toxins	3–5 days	0.01–0.1 $\mu$ g SEs
Limulus assay	Viable and nonviable Gram-negative bacteria	30–60 min	$\sim 300$ <i>E. coli</i> cells; 1–5 pg of <i>E. coli</i> LPS
Polymerase chain reaction	Microbial cells	3–5 h	1–100 cells
Reverse transcription PCR	Enteric viruses in water, food, stools	3–5 h	1–100 pfu
	Viable bacterial cells	3–5 h	1–100 cells
Multiplex PCR	Microbial cells (suitable primers)	3–5 h	1–100 cells
Dye (methylene blue)	Raw milk, meats	$\sim 8$	$10^5$ CFU ml <sup>-1</sup>
Reduction	Seafoods	8–12 h	$10^5$ – $10^4$ CFU
Radioimmunoassay	Botulinal, other toxins	3–4 h	0.1–1.0 ng SEs
Radiometry	Viable cells	2–24 h	1–10 coliforms in 6 h
Thermostable-nuclease	<i>Staph. aureus</i>	$\sim 3$ h	$10^6$ cells or 2–5 ng <i>Staph.</i> <i>enterotoxin</i>
Biosensors			
<i>lux</i> gene	Viable salmonellae	10–30 min	$\sim 10$ CFU
Ice nucleation	Viable salmonellae	24 h	$\sim 25$ cells

dehydrogenases, to transfer hydrogen from a substrate to a redox dye, which then undergoes a change in color. The rate of reduction depends on the enzyme activity, and this has been used as an index of the number of bacteria present in milk. In general, the reduction time is inversely related to the bacterial content of the sample when incubation with the dye commences.

Methylene blue is the most widely used dye and it undergoes a color change from blue to white when reduced. Resazurin, like methylene blue, is a redox indicator but unlike methylene blue, it undergoes a series of color changes from blue and mauve to pink as it is reduced. The use of these dyes is restricted to products that do not contain inherent reducing components.

**Impedance** The growth of microorganisms results in changes in the composition of the culture medium as nutrients are converted into metabolic end products. Complex uncharged molecules, such as carbohydrates or lipids, are catabolized to smaller charged molecules such as lactic and acetic acid. Charged molecules, such as proteins and polypeptides, are converted via amino acids into ammonia and carbon dioxide. As growth proceeds, these processes lead to a decrease in the overall impedance of the medium as conductance and capacitance increase. Electrical charges in microbial cultures provide a means of detecting microorganisms and their metabolic effects.

Electrical charges are a function of bacterial growth and replication.

The threshold for detection by instruments based on electrical methods such as Bactometer, Malthus, and RABIT depends upon the organisms and the media. In general, most media give detection thresholds at  $\sim 10^6$  bacteria or  $10^5$  yeasts ml<sup>-1</sup>. If the sample inoculated into the medium contains fewer organisms than this, there will be no detectable signal until the organisms have replicated sufficiently to reach the threshold number. The detection time depends upon the initial number of viable organisms present in the sample and their specific growth kinetics. Variations in growth rates of different organisms may give rise to errors in the estimation of bacterial numbers. Generally, there is an inverse relationship between log<sub>10</sub> plate colony count per milliliter or per gram and the electrical (impedance or conductance) detection time. The method has an inherent delay whilst growth occurs, generally taking > 6 h to detect  $10^5$  bacteria ml<sup>-1</sup>.

**Adenosine 5'-triphosphate (ATP) assay** The functional significance of ATP in the metabolism of living cells suggests that its measurement should be an excellent monitor of microbial activity in the sample. There are two factors that adversely affect the estimation of bacterial numbers by measurement of ATP: first, nonbacterial ATP and, second, quenching of the emitted light. Failure to destroy the

nonmicrobial ATP will give an elevated estimate of microbial ATP, and hence microbial numbers. The usefulness of ATP methods to enumerate microbial numbers is highly dependent upon the sample type. The BactoFoss (Foss Electric) is a fully automated instrument using ATP-bioluminescence for estimating the numbers of bacteria in raw milk. The instrument can analyze ~20 samples per hour and takes only 3 min to give a result. Methods based on ATP can be used to obtain real-time measurements of the hygienic status of processing equipment. Portable test kits and instruments are marketed by Biotrace, Lumac, and other companies.

**Enzyme-linked immunosorbent assay (ELISA)** ELISAs detect and amplify antigen–antibody reactions by using covalently bound enzyme–antibody molecules. The presence of the enzyme (indicating presence of the antigen) is detected by the addition of the appropriate substrate. Detection systems are usually designed to produce a color change that can be quantified by a microtiter plate reader.

ELISAs can be used in two modes, qualitatively to determine the presence or absence, or quantitatively to determine the amount of antigen present. ELISA kits often depend on the adsorption of either the antibody or antigen to a solid phase, e.g., wells of a microtiter plate, surface of plastic beads, or plastic stick. The choice of antibody (or antibodies) used determines the specificity of the ELISA assay, which can range from genus-specific to strain-specific. The principle on which ELISA methods are based usually prevents them from being used for the determination of total microbial counts. However, they can be used to detect pathogens such as *Salmonella* spp., *Listeria* spp.

**Limulus test** The *Limulus* test can be used to determine rapidly and specifically the cumulative content of Gram-negative bacteria in foods. Gram-negative bacteria produce a lipopolysaccharide (LPS) (endotoxin), which is a high-molecular-weight complex; it is not produced by Gram-positive bacteria. Present in the blue blood of the horseshoe crab, *Limulus polyphemus* is a nucleated cell called an amoebocyte, the cytoplasm of which is densely packed with granules. *Limulus* blood clots in the presence of bacterial LPS. All the necessary clotting factors are contained in the extract of the amoebocyte granules, called *Limulus* lysate. The *Limulus* test is specific for LPSs and is very sensitive. As little as  $10^{-12}$  g LPS per milliliter can be detected, occasionally even  $10^{-15}$  g ml $^{-1}$ . A single Gram-negative bacterium contains  $\sim 10^{-14}$  g of LPS.

For the *Limulus* test, a 10-fold dilution series of the sample is prepared and equal volumes of the *Limulus* lysate and diluted sample are mixed in a test tube. The test tube is then incubated before being inverted and read. If the mixture remains unchanged and runs out of the tube then that dilution of the sample does not contain LPSs. If a firm opaque gel is formed that sticks to the bottom of the tube then that dilution of the sample contains LPSs. Generally, a visual reading of the tenfold or twofold dilutions gives sufficient information about the level of LPSs present in the sample.

The limulus amoebocyte lysate (LAL) test with chromogenic substrate is faster than the gelation method, and it can be automated. The chromogenic substrate is attached to *p*-nitroaniline, that is released when reacted with the endotoxin-activated enzymes. The free *p*-aniline is read at 405 nm.

**Biosensors** The use of certain chemicals or one live organism to detect the presence or activity of another is the basis of what biosensors are. The incorporations of the *lux* and ice nucleation genes are examples of biosensors. A large number of biosensors have been constructed along the lines of the above, and several examples are noted below. *Saccharomyces cerevisiae* has been altered to express the firefly luciferase gene as a means of assessing the presence and toxicity of environmental contaminants in waters. Bioluminescence is decreased by toxins that inhibit this eucaryotic cell and the degree of toxicity is assessed by decreased bioluminescence. In a biosensor that detects the presence of Gram-negative bacteria, the green fluorescent protein (Gfp) was enhanced so that its fluorescence is quenched when it reacts with Gram-negative bacteria or LPS in water. Biosensors have been developed that can detect Gram-negative bacteria that produce acyl-homoserine lactone (AHL) molecules that are often involved in quorum sensing. AHL production is detected on agar plates after ~24 h incubation either by a color change or the production of bioluminescence around the biosensor culture, depending upon the biosensor strains used. A study of the metabolism of *Lactococcus lactis* in the gastrointestinal tract was achieved with an *L. lactis* strain that was infused with the *lux* gene. Some other uses of *lux* and ice nucleation are discussed below.

In some *Vibrio* species, bacterial luciferase catalyzes the flavin-mediated oxidation of tetradecanal with concomitant emission of blue-green light. The genes responsible for reactions of the fatty acid reductase complex (*lux* genes) have been cloned and their functions identified. One novel concept for the enumeration and identification of microorganisms requires the introduction of the *lux* genes into the

genome of a bacteriophage. The recombinant phages lack the intracellular biochemistry necessary for light production and are therefore dark. The result of phage infection is bioluminescent bacteria, which are then readily detectable.

Ice nucleating bacteria are found in a few genera. Certain species of *Pseudomonas*, *Erwinia*, and *Xanthomonas* possess ice nuclei that initiate the formation of ice in water at temperatures as high as  $-2^{\circ}\text{C}$ , compared with most inorganic ice nucleators that do not show activity until  $-8^{\circ}\text{C}$ . The phenotypic characteristic of ice nucleation is probably encoded in a single gene. Ice nucleation genes and proteins have been used as sensitive labels in ELISA immunoassays. The detection of freezing events is simplified by the use of dyes that fluoresce in super-cooled water but are quenched and change color when the water freezes.

Ice nucleation research has led to the development of the Bind assay for the rapid detection of *Salmonella* spp. The Bind assay uses attachment of a phage to its host and the expression of an ice nucleation gene after the injection of phage DNA to achieve highly specific and sensitive detection of the target organism. A range of *Salmonella* spp. has been detected at levels of less than  $10\text{ ml}^{-1}$ . The Bind assay principle could be applied to detecting a range of bacterial pathogens and typically gives results in less than 1 h but will probably require preincubation of the sample before testing. Similar advances are being made in *lux* gene technology.

**Radiometric methods** Most radiometric methods are based on the principle that microbial growth in media can be monitored by measuring  $^{14}\text{CO}_2$  released during the metabolism of radiolabeled nutrients. These methods take from 2 to 24 h to complete depending on the numbers of microorganisms present in the sample. As with impedance measurements, the detection time (the time taken for the measurement of a specific concentration of  $^{14}\text{CO}_2$ ) is generally inversely related to bacterial numbers. Radiometric methods are perhaps best suited to determining the sterility of products as they are particularly sensitive, given a sufficient period of incubation. The Bactec is a radiometric-based system.

**Nucleic-acid based methods** A number of detection and identification methods have been developed that are based on specific nucleotide sequences in RNA or DNA and several are noted in Table 2. Synopses of other related methods are presented in Table 3.

**DNA probes** Using labeled genome sequences, a probe can be made to detect for an organism in a

variety of specimens. Probes are now widely used and this wide usage results in part from the availability of a number of commercial test kits for a variety of microorganisms, mainly bacterial pathogens, and from their sensitivity and effectiveness in identifying species or strains of interest.

To apply a probe, unknown bacterial cells are treated to release single strand DNAs (ssDNA) that are affixed to a cellulose nitrate filter membrane. A laboratory probe (single strand) is made with bases complementary to those of the organism of interest on the membrane, and attached to the probe is a reporter molecule (dye, isotope, or enzyme). After the labeled probe has reacted with the ssDNA on the membrane, unreacted probe is rinsed away followed by detection of the reporter. Probes may bind to rRNA (rRNA:DNA) or to ssDNA (DNA:DNA).

A dipstick probe can be used to identify organisms in clinical or environmental specimens. It consists of adding a capture probe (containing a sequence of poly-dA or -dT bases that identifies it as a capture probe) coupled to dioxygenin as a reporter. Following destruction of unhybridized probe material, a dipstick that can hybridize with the capture probe base sequence is added. After all steps are completed, the presence of the capture probe is positive for the organism of interest. The theoretical sensitivity of a probe is  $<1\text{ }\mu\text{g}$  of nucleic acid or  $\sim 10^6$  cells. However, by use of polymerase chain reaction (PCR), the DNA of a single cell can be amplified several millionfold.

**Fluorescence in situ hybridization (FISH)** FISH permits the microscopic visualization of a nucleic acid target in a cytological context. It is primarily used to map genes to their respective chromosomal locations using labeled probes, and a similar approach might also be adapted to detect the presence of microorganisms. FISH has several advantages including the ability to visualize nucleic acids within a single cell and the sensitivity to detect one copy of the target without destroying the cell structure. The probe is usually a nucleic acid segment that is labeled with a fluorescent marker to allow detection (direct FISH) or labeled with a hapten, which require the development of a secondary reagent coupled to the fluorescent marker (indirect FISH). The target is normally a preparation of DNA or mRNA on a microscope slide. Target nucleic acids and probe are denatured and annealed, allowing the labeled probe to hybridize to the target sequences. Unbound probes are washed away and the specific hybridization signals are revealed.

**Polymerase chain reaction** By use of this method, large quantities of DNA can be made from an initial

**Table 3** Synopses of some of the newer biotyping, fingerprinting, and strain identification methods**Biotyping** (for species and strains)

**Bacteriophage typing:** The very high degree of specificity of a phage for its host cell is used to identify species and strains. Very valuable in epidemiological investigations. About 24 h required for results for most aerobic bacteria.

**Immunofluorescence:** The fluorescent antibody test is the most widely used. Antibody is labeled with a fluorescent dye and results are viewed under a microscope.

**Latex agglutination:** Antibodies are coupled to microspheres that agglutinate in the presence of homologous cells. At least  $10^7$  cells  $\text{ml}^{-1}$  are needed but results may be obtained in  $<1$  h.

**Cellular fatty acid analysis:** Total cellular or membrane-associated fatty acids are determined by GLC and both species and strains can be discerned by reference to a standard library. Several days are required for results.

**Fingerprinting** (strain differentiations)

**Ribotyping:** Using restriction fragment length polymorphism (RFLP) consisting of the restriction fragments around the rRNA genes from a particular genome to characterize bacterial strains. Total DNA is extracted and digested with selected restriction enzyme into multiple fragments ranging from 1 to 20 kb. The fragments are separated by agarose gel electrophoresis and subsequently hybridized with a labeled probe targeting 16S, 23S, or 5S rRNA genes. The length polymorphism of the hybridized fragments can be detected based on the labeling method (dye, radioisotope, or enzyme).

**MicroArray:** This is a hybridization-based technique but offers the advantage of being able to monitor the expression of thousands of genes on a single chip. One version of the MicroArray is to immobilize oligonucleotide or DNA probes to solid surface at defined positions. RNA extract or DNA from sample is eluted over the surface. Complementary binding between the probes and sample is detected by fluorescence following laser excitation. MicroArray is widely used to compare differences in gene expression. Various versions can be used to identify microorganisms as well.

**PCR:** Using a pair of primers targeting a particular gene from a specific organism and employing thermostable DNA polymerases and thermo-cycler to selectively amplify the flanking DNA fragment. The comparison is based on the size of the PCR fragment determined by agarose gel electrophoresis; therefore, a false positive result is possible. The method is very sensitive and rapid. Theoretically, the presence of even a single cell can be detected within a few hours.

**AFPL:** This patented (Keygene NV) amplified fragment length polymorphism assay is a PCR-based method that is very highly discriminating. It employs the ligation of adapters to restriction fragments followed by PCR-amplification with adapter-specific primers. Commercial kits are available, and results can be obtained within 24 h.

**RAPD:** Using a short oligonucleotide fragment the sequence of which is randomly scattered within the genome as PCR primer for random amplification of polymorphic DNA fragments from the genome. The PCR fragments can be separated by agarose gel electrophoresis and the characteristic patterns can be used for strain identification. The method is rather rapid and the procedures can be completed within several hours. However, the repeatability of RAPD sometimes is questionable.

**PFGE:** Whole cells are embedded in agarose gel and genomic DNAs are enzymatically purified and restrict digested by rare cutting enzymes *in situ*. Large restriction fragments (50–1000 kb) are separated by pulse field gel electrophoresis into a characteristic RFLP. The total procedures take several days.

**MEE:** Multilocus enzyme electrophoresis (MEE) can be used to estimate genetic relatedness among strains or species by measuring the relative mobility of cellular enzymes under nondenaturing conditions. The allelic profiles or MEE types may be used to compare isolates of the same species from different sources.

**Identification** (of species and strains)

16S rRNA sequence comparisons are in wide use to identify bacteria to the generic, species, and subspecies levels. The class *Proteobacteria* is based on 16S rRNA data and many of the new bacterial taxa are defined along these genotypic lines in contrast to the phenotypes that results from the use of general biochemical methods noted below.

Substrate test kits include those of the Enterotube, API, BioLog, and other related systems. They can be used to determine biochemical reactions of bacteria, yeasts, and molds within 1–3 days and thus aid in their identification. Some API system kits can be used to characterize organisms at the subspecies level by their capacity to utilize up to 100 substrates. The BioLog systems use carbon source metabolic 'fingerprints' to identify microorganisms.

Chromogenic and fluorogenic substrates are employed in a number of culture media to facilitate strain or species identification. BCIG or X-Gluc (5-bromo-4-chloro-3-indolyl- $\beta$ -D-glucuronic acid) is an example of a chromogenic substrate that turns blue within 24 h with *E. coli* growth while MUG (4-methylumbelliferyl- $\beta$ -D-glucuronide) is a substrate that fluoresces with *E. coli* growth.

small quantity. With the nucleotide sequence of a portion of the desired gene and laboratory-made short oligonucleotide primers that are complementary to the above gene sequence, the various steps in the PCR including 30–50 cycles will lead to a several millionfold increase in the small amount of starting DNA.

Two or more regions of a genome can be amplified during a single PCR procedure and this is referred to as multiplex PCR. If the amplified PCR products have different length, they can be resolved by use of

agarose (0.7–2%, depending upon the length of the fragments) gel electrophoresis in  $\sim 2$ –4 h. This method can be used to distinguish between botulinum toxins A, B, and E in food specimens when the specific genome sequences are employed, and as few as 100 botulinum cells per gram can be detected. If primers were designed to target genomes from different microorganisms, multiplex PCR can also be used to detect the presence of multiple microorganisms during a single PCR procedure.

Reverse transcriptase (RT) PCR (RT-PCR) can be used to detect RNA in specimens, especially ssRNA viruses. Using the ssRNA as a template, cDNA (complementary DNA) can be synthesized with the enzyme reverse transcriptase, which can further be used as a template in PCR amplification. In two-step RT-PCR, extracted RNAs are first mixed with RT and suitable primer to synthesize cDNA and then followed by adding *Taq* polymerase and PCR primer pairs for PCR amplification. In one-step RT-PCR, all the ingredients are mixed together and allowed for one cycle of reverse transcription to synthesize cDNA followed by 30+ cycles of PCR amplification. The product can be analyzed by agarose gel electrophoresis. Commercial RT-PCR test kits are available.

### Other Methods

Microbiological methods are useful for testing naturally occurring water-soluble vitamins such as the vitamin B complex. The growth response of vitamin-dependant strains of microorganisms in vitamin-free media is proportional to the concentration of the vitamin in the added test sample, or standard. Standard calibration curves of turbidity (microbial growth) versus concentration of vitamin are prepared and the concentration in the test sample estimated from its turbidity measurement. The organisms used are often specific strains of *Lactobacillus*, *Streptococcus*, and *Saccharomyces* species. Despite the fact that the microbiological technique is more cumbersome than chromatographic techniques, it is still used for those vitamins that are present in formulations at minute concentrations, as it is more sensitive

(riboflavin can typically be measured at a concentration of less than 1 µg per g) and they are preferred over colorimetric methods for foods containing high levels of Maillard browning products.

A number of microbiological methods are used in the pharmaceutical and healthcare industries. The antimicrobial preservatives – effectiveness assay is used to assess the effectiveness of a given agent within a product formulation to act as a preservative. The test product, complete with the preservative, is assessed in terms of its ability to suppress the growth of a series of test organisms under a defined set of conditions. The microbial limits test is used to estimate the total number of viable organisms within a given finished product, or raw material, and to determine the presence or absence of a specific set of pathogens. Sterility tests are performed in order to determine whether a given Pharmacopeial article is actually sterile. The procedure (direct transfer to test media or membrane filtration) by which the product is tested depends upon the physical nature of the product and the presence of any bacteriostatic or fungistatic agents within the formulation. Microbiological assays are typically used to determine the activity or potency of antimicrobial products such as antibiotics. This activity is demonstrated by a pronounced reduction in growth of the test organism. The microbiological assay remains the definitive technique because it can reveal the presence of subtle changes within the product that may go undetected if assayed by chemical means. There are two standard forms of the microbiological antimicrobial assay: the cylinder-plate assay and turbidometric assay. Both assays rely upon quantifying the degree of growth

**Table 4** Synopses of some of the bioassay methods employed to determine the effect of microorganisms on human and animal tissues

<i>Anton test</i> : A test of virulence, especially for <i>Listeria</i> spp., ~ 10 <sup>6</sup> cells are placed in the eye of a guinea pig or rabbit and conjunctivitis is observed
<i>Mouse lethality</i> : To determine lethality of microbial toxins (e.g., botulinal). Injected mice are observed for up to 72 h for lethality. Toxin serotypes can be determined by use of specific antiserum. The LD <sub>50</sub> of <i>Listeria monocytogenes</i> for normal adult mice is 10 <sup>5</sup> –10 <sup>6</sup> cells, and as few as 50 cells for infant mice
<i>CHO cells</i> . Chinese hamster ovary cell monolayers are used to assess the activity of bacterial enteropathogens after 24–30 h incubation
<i>Ileal loop assays</i> . Rabbits are most commonly used to determine enteropathogenicity of cells or toxins. Injected loop sections are examined for fluid accumulation after 18–24 h
<i>Hep-2 cells</i> . May be used to determine adherence and/or invasive potential of culture filtrates. Results for some bacterial pathogens may be obtained in <2 h while some require 24 h
<i>Vero cells</i> . Used to determine enteropathogenicity of bacteria, especially invasive potential
<i>Sereny test</i> . Used to determine virulence/invasiveness of certain bacteria by administering ~ 10 cells in the eye of a guinea pig. Eyes are examined for up to 5 days for lesions
<i>Skin tests (rabbit, guinea pig)</i> . Live animals are injected i.d. to determine vascular permeability and/or erythelial activity of microbial toxins. Results may be obtained in 18–24 h
<i>Suncus murinus</i> . This small animal (Japanese house shrew) appears to represent a good bioassay of cerulide produced by <i>Clostridium perfringens</i> . The latter has an ed <sub>50</sub> of 10–13 µg per kg
<i>Rhesus monkey</i> . The animal of choice for staphylococcal enterotoxins, which induce emesis with ~ 5 µg per 2–3 kg body weight within 5 h when administered by stomach tube

reduction of the test organism upon exposure to test product; the former detects activity through zones of inhibition on solid agar and the latter through reduced turbidity.

In addition to the direct and indirect methods for enumerating microorganisms, a large number of methods exist that are employed to identify, characterize, or profile individual cultures, and some of these are listed and briefly characterized in **Table 3**.

Although genotypic and phenotypic methods (alone or in combination) can be used to identify species and strains of microorganisms, they do not provide direct evidence for the actual role of an organism in a human or animal infectious process. A number of bioassay methods are employed to this end and they consist of the use of whole animals, animal organs or tissues, or human or animal cells (as monolayers). The more commonly used of these methods are summarized in **Table 4**.

# MICROELECTRODES

**T Zeuthen**, University of Copenhagen, Copenhagen, Denmark

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Microelectrodes are electrodes with tip areas of the order of micrometers, i.e., so small that they do not induce significant damage in the sample to be tested. Such requirements are especially important in living tissue, where microelectrodes have found their widest application; for intracellular recordings tip diameters less than 1  $\mu\text{m}$  are required. Microelectrodes can also be used in combination with recent techniques of molecular biology.

Microelectrodes are basically of four types: glass micropipettes, ion-selective microelectrodes, solid-state microelectrodes, and enzyme microelectrodes (**Figure 1**). Glass micropipettes are used to record steady-state (DC) and alternating (AC) electrical potentials. If the glass micropipette is plugged with an ion-selective membrane, the microelectrode will record a potential that is proportional to the external activity of the ion to which the membrane is sensitive. Metal microelectrodes are well suited to recording AC potentials in situations where mechanical strength is required. Metal microelectrodes can also be used for cyclic voltammetry or amperometry purposes. If a metal microelectrode made from an inert metal or carbon is maintained at a given

reduction of the test organism upon exposure to test product; the former detects activity through zones of inhibition on solid agar and the latter through reduced turbidity.

In addition to the direct and indirect methods for enumerating microorganisms, a large number of methods exist that are employed to identify, characterize, or profile individual cultures, and some of these are listed and briefly characterized in **Table 3**.

Although genotypic and phenotypic methods (alone or in combination) can be used to identify species and strains of microorganisms, they do not provide direct evidence for the actual role of an organism in a human or animal infectious process. A number of bioassay methods are employed to this end and they consist of the use of whole animals, animal organs or tissues, or human or animal cells (as monolayers). The more commonly used of these methods are summarized in **Table 4**.

# MICROELECTRODES

## Introduction

Microelectrodes are electrodes with tip areas of the order of micrometers, i.e., so small that they do not induce significant damage in the sample to be tested. Such requirements are especially important in living tissue, where microelectrodes have found their widest application; for intracellular recordings tip diameters less than 1  $\mu\text{m}$  are required. Microelectrodes can also be used in combination with recent techniques of molecular biology.

Microelectrodes are basically of four types: glass micropipettes, ion-selective microelectrodes, solid-state microelectrodes, and enzyme microelectrodes (**Figure 1**). Glass micropipettes are used to record steady-state (DC) and alternating (AC) electrical potentials. If the glass micropipette is plugged with an ion-selective membrane, the microelectrode will record a potential that is proportional to the external activity of the ion to which the membrane is sensitive. Metal microelectrodes are well suited to recording AC potentials in situations where mechanical strength is required. Metal microelectrodes can also be used for cyclic voltammetry or amperometry purposes. If a metal microelectrode made from an inert metal or carbon is maintained at a given

**Figure 1** Four types of microelectrodes. (A) Glass micropipettes; tip diameters range from 0.01  $\mu\text{m}$  to a few micrometers. The pipette is filled with a conducting salt solution and connected, for example, via a chlorided silver wire (coil) to an amplifier (triangle). The electrical circuit is completed via the reference electrode shown at the bottom of the figure. (B) An ion-selective microelectrode. It consists basically of the glass micropipette shown on the left, but the tip is closed by a liquid ion exchanger (shown hatched) or by an ion-selective glass. Some possible ion-selective microelectrodes are listed in **Table 1**. (C) A metal microelectrode or a carbon fiber electrode. It consists of a sharpened wire (shown hatched) insulated by a layer of, for example, glass or lacquer. The electrode can be connected to an amplifier (triangle) when electrical activity, e.g., neural activity, is recorded. The electrode can also be used for analytical purposes. In this case the electrode is not connected to the amplifier but to a voltage generator and an ammeter (A), shown at the top. If the voltage is varied (symbolized by the saw tooth) relative to the reference electrode, current can flow at certain potentials, e.g., when oxygen can receive an electron from or hydrogen peroxide can deliver an electron to the electrode. The electrode can record oxygen, hydrogen peroxide, or processes that can be oxidized or reduced at the metal or carbon surface. (D) An enzyme-based microelectrode. It is constructed as the previous electrode but its tip area is coated with an enzyme. The enzyme is chosen so as to catalyze a given process the substrate of which we want to quantify in the external medium. The catalysis process should result in a breakdown product that can be measured amperometrically, e.g., hydrogen peroxide as described above. Thus, the electrode is maintained at a given potential symbolized by the DC potential generator and the current is measured by the ammeter (A). In this way a glucose microelectrode can be constructed.

potential, the current can only pass the solution-electrode interphase if electrons can be provided or taken up by the chemical processes at the electrode surface. In cyclic voltammetry the voltage between the metal microelectrode and the reference electrode is varied in a cyclical manner. The voltage at which current can flow and the magnitude of the currents will characterize the chemical composition of the external media. Ambient oxygen concentrations can be measured in this way as the current flow obtained at a voltage of 600 mV relative to an Ag/AgCl reference electrode. If the electrode is prepared with specific enzymes attached to the tip area, it can be used to record substrates that in themselves do not participate in redox processes, e.g., glucose.

**Figure 2** The principle of measurement by means of an ion-selective double-barreled microelectrode inside a cell. The cell is in a bath the solution of which is grounded via a reference electrode. Each barrel is connected via a chlorided silver wire (shown coiled) to amplifiers (triangles). The reference barrel of the double-barreled electrode directly records the intracellular electrical potential, the membrane potential ( $E_m$ ). The ion-selective barrel, indicated by the plug of ion exchanger in the tip, records the sum of the membrane potential and a potential  $E_i$  related to the chemical potential of the ion in question (of activity  $a_i$ ) (see eqn [1]).  $E_i$  is obtained by electronic subtraction. The influence on  $E_i$  from other ions (indicated by index  $j$  and the valencies  $z_j$ ) can be obtained from calibration.

For potentiometric measurements (zero current), the complete measuring circuit consists of the microelectrode, the input amplifier, and a reference electrode. Sometimes a local reference electrode is needed if the electrical potential varies over short distances in the sample, for example, across a cell membrane (Figure 2).

## The Glass Pipette Microelectrode

Glass micropipettes are produced from tubes of aluminum silicate or borosilicate glass, typically with an outer diameter of 2 mm and an inner diameter of 1 mm. If the two ends are pulled away from each other while the center of the tube is heated, the tube will narrow and separate at the middle and two electrodes will form. With proper choice of heating and strength of pull, the narrowed ends of the separated glass tube – the tips – will retain an open lumen and will be continuous with the lumen at the larger end (the shaft) of the glass tube. Tip diameters as small as 0.045  $\mu\text{m}$  have been reported. The thickness of the wall at the tip is typically one-fifth to one-tenth of the tip diameter.

The electrode is filled with a salt solution and connected via a reference electrode (Ag/AgCl or calomel) inserted into the shaft to the input of an amplifier (Figure 1A). The electrode measures the

liquid junction potential between the filling solution and the external solution. In the simple case where the electrode contains the same univalent salt (of concentration  $C_2$ ), as the external solution (of concentration  $C_1$ ), this potential equals approximately  $56 \text{ mV} \times [(U - V)/(U + V)] \log(C_1/C_2)$  at  $20^\circ\text{C}$ , where  $V$  is the mobility of the cation and  $U$  that of the anion.

In the general case where the external solution is unknown, the equation for liquid junction potential takes a more complicated form. Yet, any variation in the potential between various sites of measurements can be suppressed if a filling solution of high concentration and with equal mobilities of the anion and cation (e.g.,  $1\text{--}2 \text{ mol l}^{-1}$  KCl) is employed. Thus, the working principle of the electrode depends on free diffusion of the filling solution from the tip into the sample. This has important implications. KCl will be continuously lost into the sample; if this leakage is prevented, then the electrode does not measure the correct potential. With tip diameters of  $0.1 \mu\text{m}$  (impedance of  $\sim 50 \text{ M}\Omega$ ), this leakage rarely constitutes a problem, even for intracellular recordings.

In addition to the liquid junction potential, which can be suppressed, some electrodes exhibit a so-called tip potential, which is  $\sim 5\text{--}10 \text{ mV}$ . The origin of this potential is unclear. It is associated with narrow tips and is less frequently encountered if the filling solutions are ultrafiltered before use, with a filter limit of  $0.2 \mu\text{m}$ . The tip potential can be defined as the difference in the electrode potential with the tip intact and the tip broken off. The tip potential varies in an unpredictable manner when the tip is placed in different solutions. Such electrodes should be discharged before use.

Glass exposed to water will hydrate and its electrical resistance will decrease. After 2 h of exposure to aqueous media, the resistance of the glass wall may have decreased from say 1000 to  $50 \text{ M}\Omega$ . If the impedance of the electrode is  $10 \text{ M}\Omega$ , this means that a significant shunting of the measured potential may take place. In practice, this means that electrodes ought to be made on the day of the experiment. It is also a common observation that cell debris and other biological material adheres more stubbornly to the sides of micropipettes that have been hydrated. It is often useful to change the electrode after 3–5 h of application in biological fluids.

The input amplifier for the micropipette should have an input resistance of  $10^8\text{--}10^{10} \Omega$ , easily obtained with operational amplifiers with field-effect transistor inputs. If the input is provided with negative capacitance compensation, both the capacitance of the cable that connects the electrode to the amplifier and the capacitance between the inner solution of the electrode and the external bath can be compensated

for. With proper compensation the electrode can follow fast changes in, for example, action potentials from nerves or nerve cells.

## **Ion-Selective Microelectrodes**

The micropipettes described above can be made into ion-selective microelectrodes if the tip is closed by means of an ion-selective membrane (Figure 1B). The membrane may be in the form of an ion-sensitive glass, for example, for the measurement of  $\text{H}^+$  and  $\text{Na}^+$ , or more conveniently a liquid ion exchanger (LIX), which is available for the measurement of  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{H}^+$ ,  $\text{Li}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Cl}^-$  (see Table 1). The input amplifier for the ion-selective micropipette should have an input resistance two orders of magnitude larger than the impedance of the electrode itself, i.e.,  $10^{12}\text{--}10^{14} \Omega$ . This can be obtained with operational amplifiers with field-effect transistor or electrometer inputs. The ion-selective membrane may also be placed directly on to the field-effect transistor input of an operational amplifier, a so-called ion-selective field-effect transistor (ISFET). The linear dimensions of the recording area of ISFETs can be as small as  $10 \mu\text{m}$ . To complete the electrical circuit, the amplifier of the ion-selective microelectrode must be connected to a reference electrode in the form of either a locally positioned micropipette or a large external electrode (Figure 2).

## **Construction**

The construction of an ion-selective microelectrode is most conveniently based on a micropipette made from inert glass as described above. This forms the outer housing of the electrode. If the ion-sensitive membrane is to be made from glass, tubes of ion-sensitive glass are pulled into the shape of a pipette with dimensions that allow this pipette to be fitted inside the inert micropipette. The tip of the ion-selective glass micropipette is sealed at the very tip and positioned inside the inert pipette with the tip of the inner pipette as close to the tip of the outer pipette as possible, preferably within  $10\text{--}20 \mu\text{m}$ . The two glasses are sealed together from  $\sim 100 \mu\text{m}$  from the tip for a length of  $\sim 100 \mu\text{m}$ . The electrodes last long but are relatively difficult to make. Unless special problems, such as biocompatibility between LIX and the sample are relevant, the LIX electrodes described below are preferred.

In the LIX microelectrode the ion exchanger is situated at the tip of the inert micropipette by rendering the inside of the micropipette hydrophobic and organophilic. Thus, the ion-sensitive part of the LIX microelectrode is the interphase between the ion

<sup>a</sup>These are the major interferences in a physiological experiment, the numbers are log  $K$  (eqn [1]).

<sup>b</sup>These values are relevant for experiments in normal biological fluids.

<sup>c</sup>These are values for typical electrodes, the range of impedances matches the range of tip diameters. Electrodes with smaller tip diameters can be made; this gives higher resistances and slower response time.

<sup>d</sup>These are typical response times determined by the resistance and capacitance of the electrode. There are large variations in reported values. The response time can be reduced by coating the electrode by a thin conducting surface and electronically driving this shield together with the capacitance of the connecting cable.

<sup>e</sup>Interference from carbon dioxide can be avoided if the exchanger is saturated with carbon dioxide prior to use.

<sup>f</sup>BTH 227 is suited for intracellular use; ETH 157 is suited for extracellular use.

<sup>g</sup>The response time depends on stirring around the tip.

<sup>h</sup>There are intracellular substances of unknown composition that equal ~7 mmol of Cl<sup>−</sup>.

exchanger and the external solution (Figure 1B). The siliconization is best achieved by exposing the inside of the pipette to a vapor that incorporates a layer of silicone onto the glass surface. Chloro- or amino-silanes can be used; both utilize the presence of surface-bound  $\text{OH}^-$  groups that bind to Si groups in the glass. By the treatment the  $\text{OH}^-$  is replaced by  $\text{SiC}_3\text{H}_9\text{O}$ , which renders the surface hydrophobic. The LIX is situated by a thin capillary via the shaft or by dipping the tip of the electrode into LIX. The remainder of the electrode is filled with an appropriate filling solution, preferably one that contains the ion in question at a concentration similar to that expected in the sample. This will minimize offset potentials.

### Sensitivity and Selectivity

The electromotive force of the electrode for an ion  $i$  (e.m.f. <sub>$i$</sub> ) can be approximated by the Nernst–Nikolski equation:

$$\text{e.m.f.}_i = E_r + S \log(a_i + K_{ij}a_j^{z_i/z_j}) \quad [1]$$

$E_r$  is the reference potential measured by the local reference electrode. The theoretically possible sensitivity  $S$  equals  $RT/z_iF$  where  $R$  is the gas constant,  $T$  is the absolute temperature,  $F$  is Faraday's constant, and  $z_i$  is the valence of the ion.  $S$  is  $\sim 58$  mV at  $25^\circ\text{C}$ .  $a_i$  is the activity of the ion.  $K_{ij}$  is the selectivity of the electrode toward an interfering ion of activity  $a_j$  and valence  $z_j$ . In practice, the sensitivity (or slope) will be less than the theoretical value. Typical sensitivities are given in Table 1 for electrodes with tip diameters of  $0.5\text{--}1\text{ }\mu\text{m}$ . Smaller the sensitivity the finer the tip, because of the larger relative significance of unselective shunts.

The selectivities for biologically relevant ions are also given in Table 1. For the  $\text{H}^+$  microelectrode it is seen that there is no significant influence from other ions, but the exchanger shown requires saturation with carbon dioxide. There is another  $\text{H}^+$  exchanger that does not require saturation with carbon dioxide (Fluka 95297). Therapeutic doses of  $\text{Li}^+$  are  $\sim 1\text{--}3$  mmol, and it is seen that the influence from  $\text{Na}^+$  and  $\text{K}^+$  at physiological concentrations limits the use of the  $\text{Li}^+$  electrode. With proper calibration, however, data in the physiological range can be obtained.  $\text{Na}^+$  electrodes are of two kinds: the exchanger ETH 227 is well suited for intracellular use since the relatively poor selectivity toward  $\text{Ca}^{2+}$  is irrelevant because of the low intracellular values of  $\text{Ca}^{3+}$ . It will be necessary, though, to calibrate in solutions with and without  $\text{Ca}^{3+}$  in order to obtain the true baseline when the  $\text{Na}^+$  concentration is low outside the cells. Improved selectivity for  $\text{Na}^+$  over

$\text{K}^+$  can be obtained by using an ionophore incorporating a tetramethoxyethyl ester derivate of  $p$ - $t$ -butyl calix[4]arene. The exchanger ETH 157 can be used outside cells where  $\text{K}^+$  is low and the poor selectivity of the exchanger toward  $\text{K}^+$  is of minor importance. Measurements with the  $\text{K}^+$  electrode are influenced by  $\text{Na}^+$  ions only to a minor degree and no special precautions are needed when intra- and extracellular measurements are compared. The useful range of the electrode is limited at low  $\text{K}^+$  activities, where  $0.1\text{ mmol l}^{-1}$  of  $\text{K}^+$  cannot be recognized in a solution that contains  $\text{Na}^+$  at activities of  $100\text{ mmol l}^{-1}$ . Physiological  $\text{Mg}^{2+}$  activities are in the millimolar per liter range and will be affected by  $\text{Na}^+$  and  $\text{K}^+$  concentrations in the physiological range. By careful calibration,  $\text{Mg}^{2+}$  activities as low as  $0.4\text{ mmol l}^{-1}$  can be detected.  $\text{Ca}^{2+}$  is present intracellularly in very low activities ( $10^{-8}\text{--}10^{-7}$  mol), and the electrode requires high selectivities toward  $\text{Na}^+$  and  $\text{K}^+$ . In practice, the electrode tends to be relatively slow, with time constants of several seconds. Methods with fluorescent dyes are more popular at present, yet such methods do not provide the opportunity for simultaneous recording of intracellular electrical potentials.

### Calibration

Calibration should be done in solutions whose compositions lie close to that of the sample to be tested. In this way unnecessary extrapolations are avoided and the greatest accuracy is obtained. Since the electrode measures activity, one compares the activity in the sample with the activity in the calibration solution. Sometimes the measured value is expressed as apparent concentration: it is assumed that there are equal activity coefficients in the sample and in the calibration solutions.

### Tip Diameters, Impedances, and Response Times

Microelectrodes for  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{H}^+$ ,  $\text{Li}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Cl}^-$  are usually made with tip diameters of  $\sim 1\text{ }\mu\text{m}$  (Table 1). For significantly smaller tip diameters the sensitivity will be smaller than the optimal value given in Table 1. Smaller tips may be obtained while keeping a high sensitivity by changes in the siliconizing procedure. With large resistances of the electrode, the response time will also be larger. This may be alleviated by using beveled tips, which increase the leading-off area while retaining the sharpness of the tip. Shielding and capacitance compensation built in to the amplifier may improve the response time. In summary, the size of the sample (i.e., the cell) determines the size of the tip that can be used. The physiological phenomenon under study defines the required response time. Response times

smaller than 100 ms can rarely be obtained with electrodes with tip areas of diameter 1  $\mu\text{m}$ .

### Volume Measurements

It is possible to record changes in cell volumes by ion-selective microelectrodes. The method utilizes the fact that the  $\text{K}^+$ -ion exchanger, i.e., Corning 477317, is much more sensitive to choline ions ( $\text{Ch}^+$ ,  $\log K_{\text{K}^+/\text{Ch}^+} \approx 2$ ) and to tetramethylammonium ions ( $\text{TMA}^+$ ,  $\log K_{\text{K}^+/\text{TMA}^+} \approx 3$ ) than to  $\text{K}^+$ . If cells are incubated with  $\text{Ch}^+$  or  $\text{TMA}^+$ , they usually take up these ions in small quantities,  $\text{Ch}^+$  to  $\sim 1\text{--}5 \text{ mmol l}^{-1}$  and  $\text{TMA}^+$  to  $\sim 0.1\text{--}0.5 \text{ mmol l}^{-1}$ . These levels are easily seen by the  $\text{K}^+$  electrode. Since  $\text{Ch}^+$  and  $\text{TMA}^+$  cross the cell membrane slowly, induced changes in their intracellular concentration will in many experiments reflect changes in cell volume. In this way the water permeability of the cell membrane can be obtained from the response to abrupt changes in extra cellular osmolarity.

### Metal Microelectrodes

Metal microelectrodes are used to record electrical activity in, for example, biological tissues. They have advantage over glass micropipettes in mechanical strength and durability. Their disadvantage is that they cannot reproduce slow electrical potential changes (DC changes) since their impedance is mainly capacitive. They are well suited to recording action potentials from neural tissue, but the recorded potential will be distorted owing to the complex impedance of the solution–metal interphase.

### Construction

Platinum microelectrodes can be made from platinum–iridium wire (70% platinum and 30% iridium), 0.25 mm in diameter sharpened electrolytically to a tip diameter of  $\sim 1 \mu\text{m}$  and to a length of the shank of  $\sim 5 \text{ mm}$ . The electrode can be insulated by a layer of glass (Corning 7570, borosilicate glass) that has the same thermal expansion coefficient as the platinum–iridium alloy. The sharpened wire is passed through a drop of molten glass. The tip is bared and platinum-black is deposited on it by applying a negative pulse of 5–15 V for 100 ms to the electrode with the tip immersed in a solution of platinum chloride (0.1%  $\text{H}_2\text{PtCl}_6$ , 0.25% platinum acetate, and 0.025% ammonium chloride).

Tungsten microelectrodes can be made from wire 0.25 mm in diameter that is sharpened electrolytically to a tip diameter of  $\sim 1 \mu\text{m}$  and to a length of the shank of  $\sim 10 \text{ mm}$ . The pointed wire can be insulated by dipping it into lacquer. If the tip is lifted

out first, the tip will be bared for 10–100  $\mu\text{m}$  in length.

### Electrical Properties

The resting potential of metal microelectrodes in biological tissue depends on several factors: the tissue, the material of the particular electrode, the pretreatment of the electrode, and finally the leakage current of the amplifier. The major determinant of the potential will be the magnitude and direction of the leakage current. For the platinum electrode this current cannot pass the electrode–solution interphase unless carried by an electron. The potential will therefore shift to a potential at which this can take place; thus, the potential will depend on the redox potential of the substances in the external medium. For the tungsten electrodes the resting potential will be influenced by the formation of tungsten oxides. With a leakage current of  $\sim 10^{-12} \text{ A}$ , the platinum microelectrode will typically settle somewhere between  $-0.2$  and  $+0.2 \text{ V}$  relative to the  $\text{Ag}/\text{AgCl}$  electrode, and the tungsten electrode somewhere between  $-0.4$  and  $-1.25 \text{ V}$ . For larger positive leakage currents, both electrodes will attain a positive potential of  $\sim 1.3 \text{ V}$  where oxygen and chlorine are formed; larger negative currents will result in a potential of  $1.4 \text{ V}$  where hydrogen is formed.

The small-signal impedances of the platinum and the tungsten electrodes are mainly capacitive. For the platinum electrodes the impedance is given by a capacitance of  $\sim 10 \mu\text{F mm}^{-2}$ ; the average electrode has a surface area of  $10 \mu\text{m}^2$ . The tungsten electrode has a capacitance of  $0.4 \mu\text{F mm}^{-2}$ ; the average electrode surface area is  $30 \mu\text{m}^2$ . It is noticed that platinum-black increases the effective surface area compared to the tungsten electrode.

The electrodes are mainly used to record and stimulate excitable neural tissues. When used for recording of neural activity, the electrodes are connected to an amplifier with a high-input resistance  $> 10^{10} \Omega$  and low leakage current ( $< 10^{-12} \text{ A}$ ); owing to the unstable resting potential, recordings of low frequency are filtered out. When the electrodes are used for stimulation of excitable tissues, current densities of  $100 \mu\text{A mm}^{-2}$  may often be required. In case of positive currents this will shift the electrode potential from  $+1.2$  to  $1.4 \text{ V}$ , the range of redox potentials for  $\text{OH}^-$  and  $\text{Cl}^-$ . This is because transfer of an electron from  $\text{Cl}^-$  and  $\text{OH}^-$  is the only process that can supply sufficient current. For negative currents the potential will move to  $-1.2 \text{ V}$ , because  $\text{H}^+$  will accept sufficient electrons at this potential. For positive potentials the pH around the stimulation electrode will attain values of 3, at negative currents pH 11–14

may be obtained. Such gross changes in pH must be taken into account when the condition of the tissue is considered.

## Oxygen- and Enzyme-Based Microelectrodes

The ambient oxygen concentration can be measured by metal microelectrodes. If the potential of the electrode is maintained at about  $-600$  mV relative to an Ag/AgCl reference electrode, current will flow according to the reactions  $\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}_2$  and  $\text{H}_2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow 2\text{H}_2\text{O}$ . The current will therefore be determined by the availability of oxygen and its diffusion toward the electrode surface. The electrode is usually coated with a layer of poly(vinyl chloride) or silicone rubber of a well-defined thickness in order to ensure a constant length of the diffusion for oxygen. This ensures that the current is proportional to the oxygen concentration in the medium irrespective of the position and environment of the electrode.

In principle, microelectrodes can be made specifically for a given substrate provided an enzyme exists that breaks down the substrate with subsequent formation of oxygen, hydrogen peroxide, or hydrogen, substances that can be measured amperometrically by the metal microelectrode. In this way a glucose microelectrode can be constructed from a metal microelectrode. The bared metal surface is coated with a layer of glucose oxidase that is separated from the outer solution by a layer of PVC or silicone rubber of a well-defined thickness. Provided oxygen is freely available, the rate of the process  $\text{glucose} + \text{O}_2 \rightarrow \text{gluconic acid} + \text{H}_2\text{O}_2$  will be catalyzed by the enzyme, and the concentration of glucose will be practically zero at the metal surface. The diffusion of glucose toward the metal will therefore be determined by the glucose concentration in the external medium and by the thickness of the protective membrane. Since this thickness remains constant, the rate of glucose breakdown will depend on the external glucose concentration only. The metal electrode is maintained at a potential of  $-300$  mV relative to an external Ag/AgCl reference electrode and the current will flow according to the reaction  $\text{H}_2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow 2\text{H}_2\text{O}$ . This means that the current will be proportional to the rate of  $\text{H}_2\text{O}_2$  formation and therefore to the glucose concentration in the external solution. It takes considerable skill, patience, and careful calibration to make these electrodes, and so far they have mainly been applied in research laboratories.

In some situations the electrode surface can be coated with ferrocene, which allows the direct

transference of electrons between the enzyme and the surface of the electrode.

## In Vivo Potentiometry

It was seen in the previous section that a metal surface polarized to a given potential can be used to measure oxygen and hydrogen peroxide. The same principle can be used to monitor the concentrations of substrates that are themselves oxidized or reduced, i.e., take up or give up an electron at the metal surface. It should be emphasized that the useful range of potentials in aqueous solutions is limited by the potentials at which  $\text{OH}^-$  is oxidized and  $\text{H}^+$  is reduced, about  $+1$  and  $-1.2$  V relative to an Ag/AgCl reference electrode, respectively. Important possibilities are certain neurotransmitters, the oxidation of which is best performed on carbon electrodes instead of metal electrodes.

Carbon microelectrodes are made from fibers of  $1\text{--}10\text{ }\mu\text{m}$  outer diameter. These can be inserted into and supported by a glass micropipette, and the desired recording area can be obtained by varying the length of the protruding part of the fiber. Ultimately, the fiber can be cut flush with the glass capillary, whereby a small active surface is obtained. The small size decreases the signals obtained, but the spherical diffusion geometry ensures in effect a high degree of stirring around the tip. It is also possible to sharpen the tip by gradual burning with a propane-air mixture at temperatures of  $1300\text{--}1400^\circ\text{C}$ . In this way, sharpened tips with length of  $250\text{--}500\text{ }\mu\text{m}$  can be obtained while the diameter at the very tip is less than  $0.5\text{ }\mu\text{m}$ . This enables insertion into single cells. The tapered part can be coated to expose only the outer  $2\text{--}6\text{ }\mu\text{m}$  of the tip.

It is often necessary to pretreat the carbon surface electrically; positive potentials of up to  $+3$  V and negative ones down to  $-1$  V are applied alternately for various periods of time. The precise treatment should be chosen for each specific application.

For certain purposes it is useful to coat the electrode with a negatively charged membrane. Since the electrode surface is polarized to a positive potential, such a membrane will exclude negatively charged substrates while allowing neutral ones to penetrate. One choice is Nafion<sup>®</sup>, a perfluorosulfonated derivative of Teflon<sup>®</sup>.

Differential pulse voltammetry is the method of choice when compounds with similar oxidation potentials are to be resolved. The method is based on linear sweep voltammetry, where the potential applied to the electrode is increased progressively at a rate of  $5\text{--}20\text{ mVs}^{-1}$  up to about  $+1$  V. On this ramp are superimposed step potentials of constant

amplitude and duration (e.g., 50 mV lasting 50 ms). The resulting current is measured immediately before ( $i_b$ ) and after ( $i_a$ ) the application of the step potential and the difference ( $i_b - i_a$ ) is recorded as a function of the applied potential. The method in fact records the rate of increase in current and specific oxidations will appear as peaks in the current-voltage diagram.

### Specific Applications

Carbon and ceramic electrodes have been used for quantitative and qualitative recordings of the neurotransmitters dopamine (DA), 5-hydroxytryptamine (5-HT), and their metabolites 3,4-dihydroxyphenylacetic acid (DOPAC), 5-hydroxyindoleacetic acid (5-HIAA), and L-glutamate. Nitric oxide can also be recorded. In this case the carbon surface of the electrode is covered with a p-type semiconducting polymeric porphyrin that acts as a catalyst for the oxidation of nitric oxide. Nitric oxide is responsible for the activity of the endothelium-derived relaxing factor associated with hypertension, diabetes, ischemia, and arteriosclerosis.

One of the problems of recording dopamine, 5-HT, and nitric oxide is that other substances present have oxidation potentials similar to the substrate under study. The metabolites of dopamine (DOPAC) and of 5-HT (5-HIAA) are oxidized at the same potential as their parent substances, +0.2 V for DA and +0.4 V for 5-HT. Furthermore, they may be present *in vivo* at concentrations two orders of magnitude higher than that of their parent substances. In addition, ascorbic acid present in large concentrations is oxidized in the same voltage range as DA and 5-HT. Coating the electrode with a negatively charged membrane (Nafion<sup>®</sup>) will to a large extent alleviate these problems since the membrane will keep the metabolites from reaching the electrode surface. In case of the nitric oxide electrode, the Nafion<sup>®</sup> membrane seems to stabilize the oxidation product  $\text{NO}^+$  and to reduce the

sensitivity of the electrode for  $\text{NO}_2^-$  to such an extent that the reactivity of the electrode to  $\text{NO}_2^-$  does not interfere with the recording of nitric oxide.

## What is Microscopy?

Microscopy, the use of a microscope, refers to those techniques by which investigations are made on fine details that cannot be discerned with the naked eye. It covers techniques of observation ranging from the use of a single lens or 'magnifying glass' to the

imaging of atoms, and provides information about the structure, distribution, organization, and chemical composition of objects. Some newly developed forms of microscopy technically have little in common with traditional types of microscope, but are nevertheless considered to be microscopy since they fulfill the basic function of a microscope, that of providing information about fine details in an object.

Microscopes have been used since the middle of the seventeenth century, and are now applied in all branches of scientific research, and are in routine use in education, hospitals, and industry. Indeed, it is considered that virtually all industrial products rely on the microscope at some stage, in development of the materials and techniques (metals, ceramics, polymers, food), in manufacture and testing, or in failure analysis.

The limitations of the human eye as an instrument for the study of fine detail are overcome by three important attributes of a microscope: resolution, contrast, and magnification. It is clear that magnification is a prime requirement, resulting in an enlarged image from which the sensory elements of the retina of the eye can gather more information than from the smaller, naked-eye image. Though essential, magnification is relatively easily achieved by any form of microscope, and attention should be directed principally toward resolution or resolving power: the ability of a system to make information about fine detail distinguishable in an image. The human eye can detect only variations in brightness and/or color in an image, and these variations, or contrast, must be adequately large. Some optical or chemical properties of objects cannot be discerned by the unaided eye; techniques of contrast enhancement enable information about these properties to be converted by the microscope and presented to the eye in the form of variations in brightness and/or color.

With the exception of lensless devices such as scanning tunneling and near-field microscopes, which have the same fundamental attributes though operating according to different principles, the essential feature of a microscope is the interaction with the specimen of a beam of electromagnetic waves (light) or particles that possess wave-like properties (high-energy electrons). The beam becomes modified as a result of this interaction, carrying information about the specimen, and this information is presented in the form of an image. It is important to note that with a microscope one does not observe the specimen, but an image of the specimen, which will necessarily be a less-than-perfect representation of it. Deficiencies in the quality of the image may be due to inadequate equipment or poor technique, but an important fundamental limitation is set by the laws of

physics and the phenomenon of diffraction. The essential difference between light and the other imaging agents is their wavelength, the factor that sets the ultimate limit of resolution. The conventional light microscope closely approached its theoretical limit of resolution at the end of the nineteenth century; electron microscopes have not yet reached the limit imposed by wavelength, because of the aberrations of the lenses. In addition to the limitations due to the instrument and its operation, the information content of microscopical images is subject to artifacts of specimen preparation, which may include special procedures such as sectioning, staining, and etching. Considerable skill and experience may be necessary in interpreting the image that, though it may be presented as a 'picture of the specimen', should not be accepted without critical consideration of artifacts of preparation and the origins of contrast, and the application of appropriate analytical procedures.

## Theory and Basic Concepts

Microscopes that use lenses can be classified in several ways: (1) simple, single-lens instruments (magnifying glasses) or compound microscopes using an objective lens together with an eyepiece; (2) microscopes in which the entire image is presented simultaneously as in normal direct vision, or scanning microscopes in which the image is built up sequentially, point by point, as with television; or (3) classified according to the imaging medium (light, electrons, sound waves, or other forms of radiation or particle). Despite their important differences, all these kinds of microscope have much in common, and are subject to the same fundamental limitations. The description of the fundamentals of microscopy that follows is written in terms of the conventional light microscope; the important features of other forms of microscope are described elsewhere.

### Lenses

The principal lenses of microscopes are positive or converging lenses: thicker in the center than at their edges. In the accompanying diagrams, for simplicity, lenses will be shown as single pieces of glass, or represented by the center plane of the lens (as in **Figure 1**), though in practice they consist of several lens elements of different kinds of glass, carefully designed to minimize the aberrations (defects) of single lenses.

Parallel rays of light, as if from infinity, entering normal to the center plane of a converging lens on one side are refracted so that they intersect on the other side of the lens in the focal plane (**Figure 1A**);

**Figure 1** Magnification by a single lens. (A) Lateral magnification, showing the formation of a magnified image,  $h'$ , of object  $h$ . (B and C) Angular magnification. The viewing angle is increased from  $\sigma$  without the lens, with the object O at the reference viewing distance of 250 mm (diagram b), to  $\sigma'$  when using the lens (diagram C). The size of the image on the retina is thus increased. (Reproduced with permission from Bradbury S, Evennett PJ, Haselmann H, and Piller H (1989) *RMS Dictionary of Light Microscopy*. Oxford: Oxford University Press and Royal Microscopical Society.)

the focal plane crosses the optical axis at the focal point (F). Light originating at a source in the focal plane leaves the lens as parallel rays on the other side. The distance between the focal plane and the center of a (thin) lens is known as the focal length ( $f$  and  $f'$ ). A lens has two focal planes (passing through F and F', respectively), one at each side of the lens (the front and back focal planes); in discussing the operation of the microscope it is frequently necessary to consider both of these focal planes for each lens. Rays from sources situated between infinity and one focal plane (e.g.,  $h$  in Figure 1A) are brought to a focus on the other side of the lens, between the other focal plane and infinity (e.g.,  $h'$ ). The converging action of a lens is due to the curvature of its surfaces: the more highly curved they are (i.e., the smaller their radius of curvature), the 'stronger' the lens (i.e., the shorter its focal length).

### Magnification

The term magnification is used to describe two different phenomena, both of which occur in the

microscope. A lens may form a real image, in the same way as a transparency is projected onto a screen. Distances in the image may be measured and compared with corresponding distances in the object; the ratio of these distances, derived from linear measurements in object and image, is known as linear magnification. Since these measurements are lateral to the optical axis, this should strictly be termed lateral linear magnification. By convention, the scale of a map (a reduced image) is shown as a ratio (e.g., 1:50 000); the scale of a real, magnified image should similarly be indicated by a ratio (e.g., 100:1).

The second use of the term magnification refers to that provided by a single lens acting as a magnifying glass or 'simple microscope'. Here, the lens alone provides no real image (i.e., one that may be received on a screen and measured), though we consider that we see a magnified image when the lens is used in conjunction with the eye, which must, in fact, be considered to be an essential part of the optical system.

The apparent size of an object depends on its distance from the eye, which determines the viewing angle; the closer the object, the greater the angle it subtends at the eye, and the larger the area its image covers on the retina, and the bigger it appears. At distances closer than  $\sim 250$  mm, the unaided normal human eye becomes unable to produce a sharply focused image, even though the object looks larger due to its close proximity. A lens or magnifier enables us to see such a close object in sharp focus, with an enlarged viewing angle (Figure 1B and C). In order to express the degree of angular magnification achieved, it is necessary to have a standard against which the magnified image may be compared. By international agreement, this standard is taken to be the image at the closest distance at which an 'average' person can see clearly, namely 250 mm, known as the reference viewing distance. At this distance the unaided normal eye perceives its largest sharp image of an object, and can resolve  $\sim 0.1$  mm ( $100\ \mu\text{m}$ ). A magnifier with a focal length of 25 mm provides a sharply focused image of an object held 25 mm away from the lens (one-tenth of the reference viewing distance); the viewing angle is enlarged tenfold. A magnifier thus provides angular magnification, which by convention is expressed with a multiplication sign (e.g.,  $10\times$ ).

### The Simple Microscope

Figure 1C shows how a single, positive lens can act as a magnifier. Typically, the object is situated in the first focal plane of the magnifier, and the center of the lens of the eye in the second focal plane.

The shorter the focal length ( $f$ ) of the magnifier, the larger the increase in viewing angle it provides,

and the higher its magnification. Because the focal length of a lens is inversely proportional to the radius of curvature of its surfaces, high-magnification lenses are necessarily small. Moreover, they need to be used uncomfortably close to the eye. The practical upper limit to the magnification of a simple lens is  $\sim 25\times$ , though Leeuwenhoek made his remarkable observations in the seventeenth century using microscopes with tiny single lenses magnifying several hundredfold.

### The Compound Microscope

The compound microscope achieves higher magnifications with greater operating convenience and versatility by dividing the magnifying process into two stages, first at the objective lens, which provides a real image with magnification up to  $\sim 100:1$ , and the second using a 'magnifying glass' (the eyepiece) of relatively low magnification (usually  $\sim 10\times$ ).

In the traditional design of microscope, the (transparent) *specimen* is situated just before (in front of, or below) the front focal plane of the objective lens (Figure 2A). A magnified image of the specimen (the *primary image*) is formed toward the top of the microscope tube, just as a projector images a slide onto the screen. The primary image is arranged to fall in the front focal plane of the eyepiece, where its extent is sharply defined by a field diaphragm. The eyepiece, operating like a magnifying glass, together with the

lens of the eye, transfers the image onto the *retina*. These three locations within the microscope shown here in *italics* are called conjugate planes; a feature present in one such plane will be imaged into all subsequent planes.

The primary image is a real image, an image that may be received on a screen, and in which distances might be measured. Comparison of measurements of distances in the object plane and image plane gives the lateral magnification of the primary image, which can also be calculated from the ratio of the objective-to-image distance to the specimen-to-objective distance. Since these distances are normally fixed in conventional microscope design, the magnifying power of an objective can also be considered to be fixed; this is the figure engraved on the lens mount. As with the simple microscope, the focal length of the eyepiece lens determines its magnifying power; extremely high or low values are inconvenient and unnecessary, and most eyepieces have a magnifying power between  $\sim 8\times$  and  $15\times$ .

### Numerical Aperture

The information-gathering power of an objective lens depends on its ability to collect the oblique rays leaving the object, a factor that depends on the angular aperture ( $u$  in Figure 3) subtended by the lens at the object. Because of the effect of refraction at the

**Figure 2** Ray-paths in the transmitted-light microscope showing (A) the field set of planes that are conjugate with the object and the final image and (B) the aperture set of planes conjugate with the filament and the apertures of condenser and objective lenses. (Reproduced with permission from Bradbury S, Evennett PJ, Haselmann H, and Piller H (1989) *RMS Dictionary of Light Microscopy*. Oxford: Oxford University Press and Royal Microscopical Society.)

**Figure 3** The angular aperture,  $u$ , subtended by an objective lens at the object.

**Figure 4** The effect on numerical aperture of the refractive index,  $n$ , of the medium between the object and the objective lens. In the examples shown, in (A), where the medium is air, the most oblique rays accepted by the objective leave the object at  $\sim 39^\circ$ ; with oil-immersion (B), rays leaving at up to  $60^\circ$  are collected.

surface of the specimen (**Figure 4**), the refractive index ( $n$ ) of the medium between the objective and the object must also be taken into account. Both factors combine to express the aperture of a lens in terms of a number, the numerical aperture (NA), calculated as

$$NA = n \sin u$$

Higher resolving power is provided by objectives of large NA, which in turn derives from a large angular aperture and/or an observing or ‘immersion’ medium of high refractive index (RI). In the common case of observation through air ( $n=1$ ), NA depends solely on  $\sin u$ , the maximum mathematical value of which is 1; a practical maximum value for  $u$  is  $\sim 72^\circ$ , giving  $NA=0.95$ . An oil-immersion lens, which operates through oil of  $n=1.515$ , can provide an NA up to  $\sim 1.4$ . For the mathematical relationship between NA and resolving power, see below.

## Illumination

The illuminating system of a microscope must be devised so as to illuminate uniformly a controllable area of the specimen, and also to supply the objective lenses with a cone of light of adjustable angle, to suit their respective NAs. Since the early days of microscopy, uniform illumination has been achieved by throwing onto the object with a condenser lens an image of a uniformly illuminated area, such as a cloud in the sky or the flame of an oil-lamp. Köhler devised a method of illumination suitable for use with nonuniform light sources, such as electric lamps, which would cause disturbing irregularities in illumination across the field of view if imaged directly onto the object. Köhler illumination requires the light source to be placed close to the front focal plane of a lamp collector lens, so that an image of the filament falls on the front focal plane of the condenser; this arrangement causes the lamp collector lens to act as a uniformly illuminated area, which may then be imaged onto the object by the condenser lens. In practice, an iris diaphragm is fitted just after the lamp collector, and this diaphragm, the illuminated field diaphragm, is imaged onto the specimen and used to control the area of the object that is illuminated; the plane of this diaphragm is thus also conjugate with the specimen and the primary and final images (**Figure 2A**).

A second iris diaphragm, located in the front focal plane of the condenser, acts to limit the aperture of the condenser and hence the angular aperture of the cone of rays entering the specimen. This is known as the illuminating aperture diaphragm, and is used to adjust the angle of illumination according to the NA of the objective (**Figure 2B**). Adjustment of this diaphragm has a profound effect on the quality of the image, and its correct setting is necessary to optimize resolution and contrast.

## Illumination in the Reflected-Light Microscope

In addition to the more well-known transparent objects and thin sections, microscopes are also used to study nontransparent specimens. For observations in the simplest imaging mode, bright-field (see below), specimens are typically polished to give a mirror surface, which may then be etched to provide contrast. The principles of illumination for reflected light are the same as for transmitted light, except that the objective lens also acts as the condenser, light being directed into the objective from above, by a partially reflecting surface. Illuminated field and illuminating aperture diaphragms are provided, though in different locations from those for transmitted light (**Figure 5**). A reflected-light microscope

**Figure 5** Ray-paths in the reflected-light microscope showing (A) the field set of planes that are conjugate with the object and the final image, and (B) the aperture set of planes conjugate with the filament and the aperture of the combined condenser and objective lens. (Reproduced with permission from Bradbury S, Evennett PJ, Haselmann H, and Piller H (1989) *RMS Dictionary of Light Microscopy*. Oxford: Oxford University Press and Royal Microscopical Society.)

requires fewer adjustments in use than one for transmitted light, since the condenser is necessarily aligned with and of equal NA to the objective (they are one and the same lens), and area and aperture of illumination become altered automatically with change of objective.

### Diffraction and Resolution

One of the most important fundamental interactions between a specimen and the imaging radiation is that of diffraction, a phenomenon that results from the wave nature of the imaging agent. Diffraction occurs whenever a wave motion encounters an object, but its effects assume particular importance in microscopy, where the dimensions of features being imaged may be close to the wavelength. The role of diffraction as the limiting factor in the performance of the microscope was first elucidated by Ernst Abbe in 1873.

Diffraction is described in textbooks of physics, and no attempt to explain its origin will be made here. The essential features of the phenomenon that

are important to an understanding of microscopy are as follows:

1. When radiation from a distant source encounters an object, a series of new waves are formed, centered about features within the object.
2. Waves from adjacent features reinforce one another (or 'interfere constructively') in certain directions, giving rise to diffracted beams. One of these beams (known as the 'zero-order' beam) proceeds in the same direction as the incident radiation, with 'first-order', 'second-order' (etc.) beams propagated on each side of the zero-order beam.
3. The angles between the zero-order beam and the diffracted beams depend on the wavelength of the radiation and the spacing of the diffracting features. The angles are greater for longer wavelengths and closer-spaced features (finer detail).
4. The diffracted beams arising from the influence of the specimen on the imaging radiation carry the information about the fine details in the specimen. The primary image results from the interference between diffracted beams; it is thus essential for resolution that these beams be collected and allowed to contribute to the image.
5. The ability of an objective lens to collect a cone of diffracted rays emerging at different angles from the specimen is governed by the NA of the objective.

Diffraction thus provides the basis for the dependence of ultimate resolving power on wavelength and NA, though it must be recognized that other limitations due to lens aberrations may be superimposed upon this diffraction limit. Light of shorter wavelengths (e.g., light at the ultraviolet, blue, and green end of the spectrum) is diffracted through smaller angles and is thus more readily collected by an objective than light of longer wavelength (e.g., red); larger NAs admit beams diffracted by finer detail. The relationship between these factors may be calculated from several formulae, a typical one being

$$d_{\min} = 0.61\lambda/\text{NA}$$

where  $d_{\min}$  represents the finest spacing that may be resolved,  $\lambda$  the wavelength of the imaging radiation, and NA the numerical aperture of the objective lens.

Since NA determines the fineness of detail that an objective can present to the observer, it has a relationship with useful magnification (magnification is considered to be useful if it reveals details not discernible at a lower magnification; magnification that reveals no new information, merely enlarging the image, is known as empty magnification).

Low-magnification objectives are generally also of low NA, and higher-magnification objectives require larger NAs. However, these relationships are not fixed; for a given magnification, objectives of a range of NAs are available – for example, objectives giving a magnification of 40 may have NAs ranging from 0.65 up to 1.4.

### Lens Aberrations

A simple lens constructed from a single piece of glass exhibits several defects or aberrations that reduce its performance. These aberrations are minimized in the design of modern lenses, which are constructed using multiple lens elements of different materials and carefully calculated curvatures, the details of which need not concern the user. For the aberration corrections to be effective, however, it is important that the lenses be used as specified in their design.

Chromatic aberration is the inability of a simple lens to bring radiation of different wavelengths to a focus in one plane. It may be corrected to varying degrees of perfection: the simplest objectives are described as achromatic, and the most perfectly corrected as apochromatic, with an intermediate class including the mineral fluorite or its synthetic equivalent in their construction. In the design of the original apochromatic objectives, correction of chromatic aberration was shared between the objective itself and a special kind of eyepiece, the compensating eyepiece. Most modern objectives are virtually completely corrected within themselves, and do not require a compensating eyepiece. Because of this, and the different degrees of compensation used in different designs, it is important to use the correct eyepiece for a given objective.

Spherical aberration is the defect by which radiation passing through the central regions of a lens does not have a common focus with that passing through the periphery of the lens; it is considerably more serious with lenses of larger aperture. Correction of spherical aberration requires two factors to be specified: the distance between the objective lens and the primary image (which is governed by the mechanical tube-length), and the thickness and RI of media between the objective lens and the specimen, especially the coverglass and any immersion medium. Objectives are specified for use at a particular tubelength, previously 160 mm and nowadays more commonly infinity (see below), and thickness of coverglass, typically either 0.17 mm or none at all. Unless these conditions are complied with, a poor image will result.

Recent designs make use of the 'infinity corrected' system, which provides greater versatility in adapting the microscope to new techniques. In this system, the specimen lies precisely in the front focal plane of the

objective. The imaging rays pass parallel through the microscope tube, as if to infinity, and are made to converge and form the primary image by the inclusion of a tubelens. The parallel ray-path between objective and tubelens permits the insertion of beam splitters, filters, and other devices, without requiring special provision to be made for the refractive effects of these items, as required by systems using a finite tubelength. Aberrations are corrected for an image at infinity, and the objectives are thus not interchangeable with those of conventional design.

Simple objective lenses suffer from curvature of field, and are unable simultaneously to focus central and peripheral regions of their field of view of the specimen in a common plane in the image. This defect is especially noticeable in photomicrographs. More complex objectives designed to provide a flat field are commonly available, usually designated by the prefix or suffix 'plan' included in their name.

### Contrast

The degree of contrast observed between features that constitute the fine detail in the field of view depends on the nature of the specimen, its preparation procedures, and the techniques employed in imaging. The generation of contrast depends on the various interactions between the specimen and the imaging radiation, which may be summarized in the following way:

- Absorption, transmission, and reflection
- Scattering and diffraction
- Refraction and polarization
- Phase change
- Fluorescence

When light falls on to an object, some will be absorbed, and the remainder will be transmitted and/or reflected. These effects are familiar in normal vision, and they are important also in microscopy. Small, transparent specimens, and thin sections of larger ones, are frequently studied by transmitted light, and the absorption of light by their features may be differentially enhanced by procedures such as staining. If light of only certain parts of the spectrum (certain wavelengths) is absorbed, the features appear colored. A transmitting specimen may also scatter or diffract light such that some proportion of it is no longer directed into the objective lens.

Thicker, opaque specimens are studied by the light that they reflect, either in a specular manner, as from a mirror, or diffusely. Metal specimens, for example, may be polished to a mirror finish and the features of interest differentiated by means of etching. The specimen surface must be arranged to be perpendicular to

the optical axis. Other, unpolished, specimens will reflect light diffusely.

For both transmitted- and reflected-light microscopy, there are two basic imaging modes: bright field and dark field. A bright-field image is formed when, as already described, light falls on the specimen from any direction within the aperture of the objective – from beneath or from above. With transmitted light, an empty field appears fully illuminated, and absorbing or scattering features reduce intensity locally. Similarly, a featureless, specularly reflecting specimen is a perfect mirror, providing a bright, fully illuminated field: features that scatter or absorb light again appear in dark contrast against the bright field.

In dark-field microscopy, light is arranged to fall onto the specimen from outside the aperture of the objective. An empty field in a transmitting specimen and a featureless polished surface will both appear dark; in both cases, any feature that scatters light into the objective lens will appear bright.

For low-magnification observations in transmitted light, a normal condenser can be converted for dark-field imaging by inserting a central opaque stop of suitable diameter at the level of the illuminating aperture diaphragm; for work with high-magnification, large-aperture objectives, special dark-field condensers are required. Low-magnification, reflected-light, dark-field images may be improvised by directing an intense beam of light obliquely onto the surface of the specimen. For higher-magnification work it is desirable to use a special illuminator, together with objectives that incorporate an annular illuminating path encircling the imaging lenses, thus obtaining uniform illumination from all azimuths.

The RI of specimens that transmit light must be considered in the context of contrast. It is an advantage with certain specimens (notably thin, transparent biological objects or sections in which the contrast has been provided by differential absorption of light by stains) for the specimen to be infiltrated and enclosed in a medium of RI similar to that of the object itself. This provides an undeviated optical path through the specimen, reduces scattering of light, and thus renders the object clear.

Precise determinations of RI can be carried out using samples mounted in media of known RI, or whose changes of RI with temperature have been calibrated. When the RIs of object and medium are mismatched, a characteristic bright line (the Becke line) is seen at the interface. When the RIs are matched, contrast is lost. Since RI is different for light of different wavelengths (the phenomenon of dispersion), it is possible to characterize particles by the colored fringes at their interface with the mounting medium, a procedure known as ‘dispersion staining’.

Materials that have an ordered molecular structure may show birefringence: i.e., they exhibit different refractive indices for light vibrating in different directions. Such specimens may be made to exhibit contrast by polarized light microscopy. Within such birefringent materials, light waves vibrating in different directions with respect to the orientation of the molecules travel at different velocities and have different wavelengths. These waves may interfere, and be made to show contrast in the image by the use of a pair of polarizing filters or polars, inserted into the light path one on each side of the specimen, normally with their vibration directions crossed. Polarized light microscopes may also be used to characterize materials by quantitative determination of birefringence.

Many specimens, notably living cells, are non-absorbing, yet contain features that refract differently, due to variations in RI or thickness, or both. These normally invisible properties of uniformly transparent specimens may be exploited to produce contrast by the phase-contrast technique, devised by Zernike in 1933. Small variations in refraction in the specimen give rise to differences in phase of about a quarter of a wavelength between the diffracted beams and the zero-order beam. The phase-contrast technique increases this difference to a half-wavelength, resulting in destructive interference, and hence contrast, in the image. The extra phase shift for the diffracted beams is achieved selectively, without affecting the zero order, by the simple device of illuminating the specimen with a hollow cone of light that enters only part of the aperture of the objective. A ring of zero-order light thus falls on a defined area of a ‘phase plate’ within the objective. The diffracted light falls on the remainder of the phase plate, which is arranged to have a suitably greater optical thickness than the area through which the zero-order passes, so that the diffracted light acquires the necessary further one-quarter-wavelength phase difference. A characteristic of a phase-contrast image is a bright or dark halo that surrounds each contrasted feature; in direct observation this can be considered to enhance the contrast, but it may become an undesirable artifact if the images are to be used for quantitative work. Phase-contrast microscopy has been of great importance in the development of cell biology. It can also be used for observation of small height differences in reflecting specimens, but for such applications it has been largely superseded by differential interference contrast (DIC) (see below).

A more recent method of generating contrast from small phase-differences between the rays leaving an object is that of DIC, especially as developed by Nomarski. In this system, two images of the object are superimposed, laterally displaced by a distance so

small that it cannot be resolved by the objective in use. This is achieved by dividing each illuminating ray into two components using as a beam-splitter a 'Wollaston prism' situated below the condenser. Differences in RI within a transmitting specimen, or height differences in a reflecting one, cause phase differences between the members of each pair of beams. A second Wollaston prism behind the objective recombines the two beams, which then interfere, their phase-differences giving rise to contrast in the image. In order to function in this way, the Wollaston prisms must be used between crossed polars, as in polarized-light microscope. DIC in reflected light microscopy requires only one Wollaston prism, situated in the objective, which also acts as condenser.

Because its contrast results from a unilateral displacement of beams, DIC provides directional contrast within the image: the specimen appears as if illuminated from one side, and is perceived as if 'three-dimensional', an appearance that may genuinely represent the third dimension, or which may be an artifactual expression of differences of RI. DIC provides a high-resolution image that lacks the haloes of phase contrast, and has excellent 'optical-sectioning' properties for imaging selected planes of focus.

Fluorescence is the selective absorption of energy from radiation of short wavelength, followed very closely by the emission of radiation of longer wavelength. In microscopy, fluorescence is used to demonstrate features that either have the inherent property of fluorescing, or features to which a fluorescent marker (fluorochrome) can selectively be attached (for example, by the techniques of immunology, which are beyond the scope of this review).

Fluorescence microscopy has progressed from bright-field and dark-field transmitted-light configurations, to the now almost universal epi-fluorescence system. In essence, the modern epi-fluorescence microscope is similar to the bright-field reflected-light instrument described above, but with several important differences. It must be provided with a source of intense illumination, particularly rich in the shorter wavelengths that are required to excite most fluorochromes. In place of the partial reflector above the objective, the epi-fluorescence microscope has a special 'dichroic' mirror – a beam-splitter designed to reflect into the objective that part of the spectrum required for excitation of fluorescence, and to transmit the longer-wavelength light emitted by the specimen, from which the image is formed. The dichroic mirror is used in conjunction with carefully chosen filters so that their combined properties match the requirements of the absorption and emission spectra of the fluorochrome. Use of large-aperture objectives is especially desirable in fluorescence microscopy, to

provide not only high resolving power but also the brightest possible image, in order to maximize the sensitivity of the technique. The light transmission of an objective depends on the square of the NA; since the objective lens acts as both condenser and objective, and light passes through it twice, brightness in fluorescence microscopy is proportional to the fourth power of the NA of the objective.

### Confocal Scanning Light Microscopy

Many specimens for microscopy are translucent, with areas of interest lying beneath the surface. When they are observed in bulk, rather than physically cut into thin sections, whether by transmitted or reflected light or by fluorescence, light will reach the image from out-of-focus planes above and below the features of interest within the specimen. Confocal microscopes are designed to exclude from the image light arising from out-of-focus planes.

Illumination from a small source, usually a laser, is imaged as a small, intense spot of light in the plane of focus within the specimen. Since most confocal microscopes are used for epifluorescence or for reflected light, this spot is imaged onto the specimen by the objective lens; a corresponding design for transmitted light is theoretically possible though practically more complex. Light returning from this spot in the plane of focus is imaged onto a small hole that is accurately located in the primary image plane. The small source, the illuminating spot in the specimen and the 'pinhole' in the primary image are all arranged to be in planes that are conjugate, and are thus described as 'confocal' – in focus together. Two important consequences arise:

1. The illumination of features within the specimen that lie above and below the plane of focus will be considerably less intense than that in the plane of focus, since the rays from the source will either not yet have fully converged and concentrated their energy, or they will have diverged after the plane of focus.
2. Features above or below the plane of focus will be imaged as points lying above or below the confocal pinhole in the primary image plane; only a small proportion of the light from each of these out-of-focus features will pass through the pinhole.

Out-of-focus features are thus effectively ignored because they are illuminated less intensely and very little of the light from their images is collected.

Thus described, the confocal microscope collects light from only one spot within the specimen. Larger areas are sampled by scanning the specimen against a stationary beam or, more usually, by using mirrors to scan the beam in a raster pattern against a stationary specimen. Light passing through the primary image

pinhole is collected by a detector, and the output may be used to modulate the brightness of a television tube scanned in unison with the raster on the specimen. Images are normally digitized and stored in computer memory, and may be combined and manipulated to present information about the specimen as required.

In contrast to this electronic system, there is another approach to confocal imaging, the tandem scanning microscope, which uses a spinning disc to scan the specimen with a large number of beams simultaneously, and presents its image directly to the eye or photographic camera. This system may provide faster scanning than the single-beam electronic system, and thus has applications in studying dynamic events.

### Advantages and Limitations of Light Microscopy

The light microscope has many advantages over other forms of microscope. Light microscopes are extremely versatile instruments. They can be used to examine a wide variety of types of specimen, frequently with minimal preparation. Light microscopes can be adapted to examine specimens of any size, whole or sectioned, living or dead, wet or dry, hot or cold, and static or fast-moving. They offer a wide range of contrast techniques, providing information on the physical, chemical, and biological attributes of specimens. The image from a light microscope is presented in color. It can be observed with the eye directly, recorded by photographic, video or computer techniques, and image components can be analyzed. And the instruments themselves are

(relatively) inexpensive, small, require no vacuum, and are undemanding of operating conditions, services and maintenance.

The principal limitation of the light microscope is its resolving power. Using an objective of NA 1.4, and green light of wavelength 500 nm, the resolution limit is  $\sim 0.2 \mu\text{m}$ . This value may be approximately halved, with some inconvenience, using ultraviolet radiation of shorter wavelengths. By good fortune, however, the resolving power of the light microscope is adequate for many areas of work in the biological and physical sciences.

### Introduction

Microscopic techniques are primarily used to determine the structural characteristics of a specimen under study. Light microscopy is used to show the overall distribution of different cell types and tissues

within an organ, and electron microscopy provides structural details at the cellular and subcellular levels. However, both light and electron microscopy can also provide information about the chemical composition of a specimen under study, although this capability is often not realized. There are a number of occasions in which such information may be required: in the biological field these include identification of elements from external sources, e.g., chemical pollutants, administered drugs, food contaminants; identification of inclusions in pathological diagnoses; the study of physiologically important elements; and as an aid in the study of histochemical methods. In this article, the stains that can be used for detection of elements at the light microscope level will be introduced, the basic theory underlying the ability to detect elements using electron microscopy (EM) will be outlined, precautions that need to be undertaken for analytical studies will be highlighted, and the major areas of application will be reviewed.

## Light Microscopy

Light microscopy can be used to demonstrate the presence of chemical elements at the tissue level. For example Perl's Prussian blue method is used for the detection of iron(III) and Von Kossa's silver reaction for the detection of bound calcium; other reactions can be used to detect gold, copper, lead, and zinc. It should be noted that these methods detect the bound form of an element; any free forms will generally be lost during the fixation period. For the detection of free calcium, light or confocal microscopy using fluorescent dyes have superseded the more traditional staining methods. In general, light microscopy is limited by both the range of elements for which stains are available and by the resolution of the light microscope, which confines observations at best to the level of individual cells. For unambiguous detection of elements and their localization at the cellular and subcellular level, EM techniques are required.

## Electron Microscopy

### Signal Generation

When a specimen is examined using an electron microscope the incident electron beam interacts with atoms in the specimen, leading to the generation of a number of signals that carry information about the chemical nature of the specimen being examined. In elastic scattering events electrons are deflected by atomic nuclei in the specimen and leave the specimen without loss of energy; these electrons contribute to the backscattered electron signal, which gives

information about the atomic number of the atoms in the specimen. During inelastic scattering events energy is transferred from the incident electron beam to individual atoms in the specimen. These interactions lead to the generation of a number of signals. X-rays are generated as a consequence of the interaction between electrons of the incident beam, causing ejection of orbiting electrons from the atomic nuclei of the specimen, the energy of the emitted X-ray being characteristic of the atomic number of the element in which the original interaction occurs and of the orbital shells involved. Collection of these X-rays and analysis of their energy forms the basis of the technique of electron probe X-ray microanalysis (EPXMA), the EM technique most widely used for the study of biological specimens. Electrons that traverse the specimen suffer either no energy loss or lose the amount of energy that is imparted to the specimen during ionization events. Thus analysis of the transmitted electron signal also yields information about the elemental composition of the specimen and forms the basis of the technique of electron energy loss spectroscopy (EELS), which is increasingly being used for the study of biological materials.

### Detection Systems

Both techniques require that the microscope be fitted with suitable detection systems. For EPXMA two types of detector are available, wavelength-dispersive (WDS) and energy-dispersive (EDS) spectrometers. EDS systems are most widely applied in biology since these systems are easier to use, are capable of detecting a number of elements simultaneously, and require lower beam currents than WDS systems. A typical X-ray spectrum obtained using an EDS system (**Figure 1**) consists of a series of peaks superimposed upon a slowly varying curved background. Peaks in the spectrum denote the presence of a given element in the irradiated area: the area under the peak is proportional to the concentration of the element. Thus EPXMA is capable of providing both qualitative and quantitative information about the elemental content of the area under study. Elements of atomic number ( $Z$ ) greater than 11 can be detected if the usual beryllium-windowed EDS detector system is used; for the detection of elements of lower atomic number a thin-windowed detector is needed.

Two types of detection system are also available for EELS. Parallel detection spectrometers are fitted below the viewing chamber in a transmission electron microscope (TEM) or scanning transmission electron microscope (STEM). These spectrometers allow the detection of EELS spectra, which are plots

**Figure 1** An X-ray energy spectrum obtained from the analysis of a freeze-dried tissue culture cell. The spectrum is essentially a histogram plot of the number of counts against the X-ray energy. The spectrum consists of peaks that correspond to characteristic X-ray emissions from different elements. The curved background under the peaks is derived from the X-ray continuum radiation.

of the scattered electron intensity as a function of the decrease in kinetic energy (i.e., energy loss). The main component of the EELS spectrum is the intense zero loss peak. At higher energy losses steps or edges are superimposed on the decaying background intensity; these correspond to the excitation of inner shell electrons and can be used to detect both the presence of an element in the irradiated area and for quantitative analysis. In addition, variations in the shape and intensity of the edge structure can provide information about the ionization state of the atom.

The second type of EELS system is fitted in the column of a TEM and forms a specialized instrument. This spectrometer is sometimes called an imaging filter, and the technique is called electron spectroscopic imaging (ESI). In this type of instrument the entire inelastic image at a specific energy loss is captured by means of a 2D detector, allowing the distribution of a specific element to be obtained rapidly over a large sample area. In this mode thicker specimens (up to 1  $\mu\text{m}$ ) can be analyzed; however, using this type of instrument, spectral information has to be recorded one energy loss at a time.

### Types of Microscope Used

An EDS system can be fitted to a scanning electron microscope (SEM), TEM, or STEM. A TEM offers the ability to undertake analysis in small areas of thin sections of the specimen and is used when high-resolution analysis is required, whereas a SEM is used for the analysis of larger areas of the surface of bulk specimens and, in general, has much lower spatial resolution. EELS is a technique using a TEM or STEM.

## Capabilities

EPXMA and EELS are complementary techniques for the study of biological specimens. Of the two EPXMA is much simpler, the focusing of the beam onto the area of interest producing a spectrum in which the presence, or absence, of an element of interest is easily determined. All the elements present in the area of analysis are detected in a single analytical run. This has advantages: it eliminates the need for sequential screening for different elements and can also reveal the presence of unsuspected elements. However, it must be realized that the technique can be used to detect nuclides of elements only, and no information about the chemical state of the element can be inferred.

EPXMA is capable of providing information with high spatial resolution. In thin sections (100 nm thick), spatial resolutions of the order of 10–20 nm have been reported. This figure depends on many factors such as the type of instrument used, the internal microscope geometry, the electron emitter, the accelerating voltage, and the thickness and composition of the specimen. The spatial resolution decreases as the specimen thickness and/or the mass under the beam increases; the resolution is also decreased with lower accelerating voltages. A minimum detectable mass of  $10^{-18}$  g of iron has been obtained in a single analytical run of 100 s. However, for biological applications the minimum detectable concentration of an element in the specimen mass is more relevant. In a thin section a minimum detectable concentration in the region of 1 mmol per kilogram of dry mass of the specimen localized under the beam should be possible with a practical analysis time of 100 s. This sensitivity is low compared with other techniques, for example, atomic absorption spectroscopy. In consequence, EPXMA cannot be used for detecting trace amounts of elements evenly dispersed throughout a matrix.

EELS analysis is inherently more difficult to perform than EPXMA, and often EPXMA may be carried out initially for the purpose of localization of a specific element before EELS analysis is carried out. EELS is generally carried out with a field emission source so that probe diameters of the order of 1 nm can be achieved, making this a very high-resolution method of analysis. Due to the higher collection efficiency, EELS is also more sensitive than EPXMA. Recently it has been shown that it is possible to detect single atoms of iron and calcium in isolated biological macromolecules. As stated previously, the two techniques are complementary. The elements Na and K, which are important in many biological systems, are poorly detected in EELS but easily detected

with EPXMA, whereas the superior sensitivity of EELS makes it ideal for the detection of calcium, which is poorly detected in EPXMA because of overlap of the Ca  $K_{\alpha}$  by the K  $K_{\beta}$  peak.

## Factors That Need to Be Taken into Account when Interpreting Microanalytical Data

### Specimen Preparation

Both EPXMA and EELS are used to measure the elemental content of a specimen as it exists under the beam in an electron microscope. Therefore, great care must be taken to ensure that the methods used for specimen preparation neither remove elements from nor add elements to the specimen. The exact method to be used for specimen preparation will depend on the form of the specimen and the objective of the study. Brief outlines of some of the

methods that are used for specimen preparation are given below.

Conventional methods used for the preparation of biological material both for light microscopy and EM consist of fixation, dehydration, and embedding. These procedures result in increased permeability of the cell membrane with resultant loss or redistribution of mobile intracellular elements. Sections are then stained, resulting in the deposition of elements onto the specimen so that the resultant spectrum is not representative of the elemental composition *in vivo* (Figure 2). In consequence, such preparation methods are rarely used when the specimen is intended from the outset for microanalysis.

For the study of the diffusible elements the specimen needs to be cryoprepared to arrest the physiological processes and to prevent redistribution of the elements by diffusion during the subsequent steps before analysis. Once the specimen has been

Individual cells, their nuclei, the mitochondria, the Z-lines, and the myofilaments are clearly seen. (B) A heart muscle cell prepared by cryofixation and cryosectioning. Although the cellular structures are the same as in (A), the details are not as distinct. (C) A spectrum derived from material as in (A). The elements that can be identified are Cu from the grid and Os, Pb, and U from the stain. The only element that can be detected from the specimen itself is S. (D) A spectrum derived from cryoprepared heart tissue. Here the major inorganic elements – Na, Mg, P, S, Cl, and K – are detected.

cryofixed, the low temperatures need to be maintained to prevent ice-crystal growth, which may cause redistribution of ions. The specimen can be maintained in a frozen-hydrated state and analyzed as a bulk specimen in a SEM, provided that a suitable cold stage and an efficient cryotransfer device are available. Alternatively, the frozen-hydrated specimen can be sectioned at a very low temperature (below  $-140^{\circ}\text{C}$ ) and analyzed as a section in the frozen-hydrated state.

### Treatment before Fixation

When investigating diffusible ions it is necessary to consider that treatment of the specimen before cryofixation may affect the results. For example, dicing tissue into small pieces before cryofixation is not suitable for highly metabolically active tissues such as the heart. It has been shown that in this tissue redistribution of ions can occur in times as short as 10 s. Similarly, in other tissues any delay between harvesting and fixation gives the possibility of element redistribution. In addition it has been shown that treatments such as the use of local anesthetics when taking skin biopsy samples can also affect elemental content.

### Specimen Stability

Most elements are stable under the conditions used for analysis; however, some problems have been encountered in the analysis of halides that can be labile if organic matter is absent from the specimen. The loss of sulfur from organic matrices has also been reported.

Under the conditions used for EDS analysis, loss of mass from the specimen matrix inevitably occurs, and this is a special problem with frozen-hydrated material. The loss from thin (100–200 nm) frozen-hydrated sections is so severe that they may be etched away during an analytical run. The loss of specimen mass also has implications for quantitative studies. The Hall method, which measures the mass of a given element per unit mass of specimen, is most frequently used for the purposes of quantification, correction factors being obtained by comparison with suitable standards. Standards that closely resemble the specimen in the composition of the organic matrix need to be used to avoid differences in mass loss between the standard and the specimen, producing errors in quantification. Mass loss can be reduced through the use of a cold stage and by lowering the beam current used for analysis.

### Peak Overlap

When an EDS detector is used, the characteristic X-ray emissions form a Gaussian peak rather than a

**Table 1** Some elements encountered in EPXMA of biological specimens that emit overlapping peaks

<i>Element</i>	<i>Interfering line</i>	<i>Line interfered with</i>	<i>Origin</i>
Pb	M	S $K_{\alpha}$ , Cl $K_{\alpha}$	Stain
U	M	K $K_{\alpha}$	Stain
Os	M	P $K_{\alpha}$ , S $K_{\alpha}$ , Cl $K_{\alpha}$	Fixative
As	L	Na $K_{\alpha}$ , Mg $K_{\alpha}$	Buffer
Ag	L	Cl $K_{\alpha}$ , K $K_{\alpha}$	Precipitating agent
Au	M	P $K_{\alpha}$ , S $K_{\alpha}$	Grid
Cu	L	Na $K_{\alpha}$	Grid
K	$K_{\beta}$	Ca $K_{\alpha}$	Naturally occurring

discrete line in the spectrum (Figure 1). In addition, the spectrum from a sample containing heavy elements may contain a large number of peaks due to L and M emissions. In consequence, some characteristic peaks may be partly or completely overlapped by peaks from a second element (Table 1) making both the identification of the peak and quantification of the number of counts under the peak difficult. The fitting routines in modern EDS analytical software are, however, usually capable of separating such overlaps. It is important that the spectrometer be calibrated on a regular basis to eliminate the effects of spectral drift, which can introduce errors in quantification. Specimen preparation methods that eliminate the addition of contaminating peaks should be adopted.

### Extraneous Radiation

In EDS the production of extraneous radiation is a problem, especially in TEM. During the irradiation of the specimen, electrons are scattered, and both characteristic and continuum X-rays are produced from materials in the surrounding area, such as the grid, the specimen support, and the lens pole pieces. Such extraneous contributions may cause errors by masking elements present in the specimen and by production of excess continuum, which causes problems in quantification.

Production of extraneous radiation from the column can be minimized by ensuring that the instrument is well aligned. Thick apertures should be used to prevent X-rays generated higher in the column from reaching the specimen, and the objective aperture should be removed during analysis to eliminate X-rays from this source. Several different types of grid should be used when pathology specimens are being examined. In quantification X-rays produced by the grid and specimen support can be corrected for, provided they are not excessive and there is a characteristic peak from which the continuum contribution can be determined.

## Applications

### Applications in Pathology and Medicine

One of the major applications of EPXMA is as an aid to pathological studies. Frequently, unidentified objects are found in specimens that have been subjected to routine histopathological examination. Determination of the elemental composition of such objects may be required for several reasons. The elements may be endogenous or may come from exogenous sources. Endogenous sources include errors of metabolism that lead to large accumulations of elements such as copper or iron, which are normally only found in trace quantities. The accumulations are often found in lysosomes of the liver cells (**Figure 3**). Identification of the element involved can aid in diagnosis. However, accumulated particles more usually result from external sources, and the identification of their elemental content may be the first step in an investigation that could have legal, public health, or medical implications. Diseases of the lung (pneumoconiosis) can occur through exposure to metals or other substances in the workplace, for example, asbestosis or silicosis. EM is used both as a means of quantifying the mineral burden in the lung and of identifying the causative agent. Granulomas can occur as a consequence of the application of cosmetics, for example, titanium and zirconium in

deodorants, or even as a result of medication: some ointments contain metals such as zinc. Titanium is also found as a food additive and as a whitening agent in toothpaste; EPXMA studies have linked this element to inflammation in the gut. Drugs taken internally may result in depositions both at and away from the expected site of action, for example, gold-containing compounds used in the treatment of arthritis, platinum-containing drugs used in cancer chemotherapy, and iodine found in contrast media. EPXMA has also been used to investigate reactions of the body to prosthetic implants such as the localization of silicon in the periprosthetic capsule surrounding breast implants. One area of great interest is the interface between joint prostheses and the body. EPXMA has been used to determine the composition of wear particles found in tissue near the prostheses and also to provide evidence that corrosion of the implant may occur within the body. Some of the applications of EPXMA in pathological studies are shown in **Table 2**.

The previous paragraph might suggest that micro-analytical techniques are only used in medical applications when complications occur. However, increasingly these techniques are being used beneficially as research tools. ESI has been used to track the effect of phlebotomy on iron deposits in hemochromatosis patients. Another area in which much

**Figure 3** Identification of the elemental content of an inclusion in a pathological specimen. (A) An unstained transmission electron microscope image of a thin section from a liver biopsy: N, nucleus; M, mitochondria. The lysosomes contain electron-dense deposits. (B) An X-ray spectrum produced by focusing the electron beam onto the specimen shows the deposits contain iron. (C) A map of iron distribution in the specimen shows that the element is confined to areas containing the deposit.

**Table 2** Some applications of EPXMA in pathology using conventionally prepared specimens

Specimen	Medical problem	Element
Nail clippings	Cystic fibrosis	Na, Cl
Hair, skin	Allergy/dermatology	Cu, Fe, Si, Ni
Liver biopsy	Hemachromatosis	Fe
Liver biopsy	Wilson's disease	Cu
Liver biopsy	Hepatitis/cirrhosis	Fe, Cu
Liver biopsy	$\beta$ -Thalassemia	Fe
Bone, cartilage	Osteoarthritis	Cu, P, Au (drug treatment)
Bone, cartilage	Failed implant	Co, Ti
Intima	Atherosclerosis	Ca, P
Lung biopsy	Pneumoconioses	Asbestos, Si, Pb, etc.
Breast biopsy	Implant	Si
Urine	Renal stones	Ca, P

effort is being devoted is in the development of new biomaterials, with the objective of producing implants with better properties of biocompatibility.

### Pollution Studies

Human activity has begun to affect the environment in which we live, resulting in contamination that affects us, as well as other organisms. Understanding the deleterious effects of pollution requires the ability not only to identify the toxic element itself but also to localize it to its site of action and to correlate the presence of the pollutant with structural and functional changes within cells, tissues, and organelles. From its beginning, EPXMA has been used widely in pollution studies. The more traditional role has been in the study of heavy metal uptake by invertebrates, which, like plants, are the first part of the food chain exposed to the contaminated environment. EPXMA has been and continues to be a valuable tool in elucidating the pathways by which these animals are able to avoid the toxic effects of metals in their diet (Figure 4 and Table 3).

More recently there has been an increased emphasis on air pollution since episodes of pollution have been correlated with increased morbidity and mortality in susceptible groups. Here EM coupled with image analysis and microanalytical techniques gives information at different levels in the pollution pathway (Table 4). The morphology and elemental composition of particles collected from ambient air can be identified and the number and composition of particles present in bronchial lavage fluids and in alveolar macrophages determined. The technique of EELS with its ability to differentiate between oxidative states of metals such as iron, and thus assist in determination of their hazard potential, has great potential in this area.

**Figure 4** (A) Transmission electron micrograph of a region of an ultrathin, freeze-dried cryosection of a propane-plunged hepatopancreas from a terrestrial isopod, *Oniscus asellus*, collected from the vicinity of an abandoned metalliferous mine where the soil was heavily contaminated with Cd, Pb, and Zn. Note the two S-cells (s), containing characteristic, electron-opaque, Cu-rich granules; one cell profile displays a prominent nucleus (n). The field also contains part of a B-cell (b) with floccular, Fe-rich granules. (B)–(D) Pairs of superimposed X-ray distribution speed-maps (i.e., qualitative maps) obtained in a JEOL JEM-1210 TEM equipped with a Link ATW Pentafet detector (138 eV resolution) and Link ISIS analyzer (Oxford Instruments) operated under the following conditions: accelerating voltage, 120 kV; filament current, 10  $\mu$ A; condenser aperture, 200  $\mu$ m; spot size '1' in fine probe mode, producing a convergent beam  $\sim$ 100 nm in diameter scanned by the ISIS system; objective aperture withdrawn; total map acquisition times, 30–60 min. The maps are slightly rotated relative to the imaged area. Note that the three maps (B)–(D) confirm that the S-cell granules are Cu containing and that these granules are capable of sequestering the nonessential metals Cd (B) and Pb (D); the B-cell granules are predominantly Fe containing (C) and, not surprisingly, do also sequester the 'borderline' metal Pb (C) but possibly not the 'Group B' Cd (B), a metal whose affinity for sulfur-donating ligands is much stronger than its affinity for oxygen-donating ligands. (This figure was provided by Dr. AJ Morgan and Ms C Winters of the Department of Applied Biology, University College of Wales, Cardiff.)

### Physiologically Important Ions

The diffusible ions of chemical elements play a central role in cell function. Controlled movement of these ions across cell membranes and sequestration at different sites within the cells are known to underlie many different events, such as the transmission of nerve impulses, the contraction of muscle, and the initiation of cell division. In consequence the study of the cellular and intracellular distributions of these elements is of great interest in physiology. Although microanalytical techniques have traditionally been used to study isolated, physiologically active

preparations, there has been increasing use of *in vivo* freezing techniques and use of cells in culture.

The point analysis mode is used specifically to determine the concentration of the diffusible elements at the cellular level in complex tissues, in cells in culture, and at the subcellular level in individual cells. Under these circumstances information is provided that is not available from other techniques and that complements the information on ionic activities commonly obtained using ion-selective electrodes or fluorescent dyes. In addition, mapping techniques allow the investigation of 2D spatial distributions of elements at the nanometer level in intracellular compartments, yielding information that again cannot be provided by other techniques.

Cells in culture represent a simple system for study in which experimental conditions are easily controlled. An additional advantage is that some of the problems that are encountered in the preparation of whole tissues for microanalysis can be circumvented. Cells grown in suspension can be prepared quite simply by centrifugation to form a pellet that can then be cryofixed and cryosectioned before analysis using a TEM. Such cells can also be collected on a filter for analysis in a SEM. Cells that normally grow as adherent monolayers can be grown on plastic film-coated gold or titanium EM grids. The grids are then removed from culture and washed rapidly to remove the overlying medium, and the cells freeze-dried and analyzed as whole mounts either in a SEM or a TEM (Figure 5 and Table 4).

**Figure 5** A scanning transmission electron micrograph of osteoblast cells grown on Pioloform-covered gold EM grids. Details of the cell components such as the large ovoid nucleus and mitochondria can be seen. Although the substrate is unusual, it does not affect the growth characteristics of the cells, which readily form a monolayer.

In physiology EPXMA is used to study changes in element distribution in normal tissues in response to different types of stimulation and is also used to investigate the effects of disease, an area sometimes referred to as pathophysiology. There is currently much interest in determining the roles of the mitochondria and the endoplasmic reticulum as sources

and sinks of the signaling molecule calcium and the interplay between these two organelles under different conditions of stimulation. Undoubtedly a significant contribution of this technique to the understanding of cell physiology has been the demonstration that nonuniform distribution of different elements within the cell can occur. Gradients of sodium concentration have been shown to exist within the first 100 nm of the sarcolemma of heart cells under conditions of stimulation. Similarly it has been shown that mitochondria close to the plasma membrane of neuronal cells accumulate calcium under stimulatory conditions. Some applications of microanalytical techniques in physiological studies are shown in Table 5.

### Botanical Applications

There is now an increase in the number of studies that use EPXMA for the study of plant cell physiology. The main problem with plant material is that large ice-crystals tend to form in the aqueous vacuoles of plant tissue on cryofixation, making cryosectioning difficult, so that the preparation route of cryofixation, cryosectioning, and freeze-drying, which is favored for the preparation of animal cells/tissues, is generally not used. Instead a variety of preparation procedures have been adopted for the study of plant materials. In the botanical field there is considerable interest in determining the composition of sap in relation to transpiration rates in plants, and it has been shown that this can be accomplished successfully by use of planed, bulk frozen-hydrated plant tissue or by using micropuncture techniques followed by analysis of the fluid droplets. Another major area of research is the adaptation of plant cells to their environment. Plants often colonize harsh

environments such as spoil heaps from mines and can also become adapted to increased salinity. EPXMA is an invaluable tool for investigating the mechanisms of tolerance of toxic materials and has been used to show that elements such as lead are sequestered at the cell wall and within vacuoles but not in the cytoplasm, microsomes, nucleus, or nucleoli.

### Introduction

Most foods are of biological origin, and processing changes their nature to varying degrees. Transitions such as grain → flour → bread, muscle → meat → salami, and milk → curd → cheese may be used as examples of foods that undergo these changes. All foods may be categorized according to specific structural characteristics. These include liquid foods that are in the form of suspensions and emulsions (beverages such as milk, fruit and vegetable juices, dressings, toppings, etc.), foamed foods (whipped cream, marshmallows), viscous foods with a low fat content (yogurts, jams, puddings) or a high fat content (dairy spreads, margarine, peanut butter), solid foods (meat, fish, bread), and powders (flour, milk powders, spices). Frequently, finished foods are combinations of these various groups. The approach used in microscopic analysis depends upon the nature of the food and the objective of the examination. The history of food microscopy, and the principles of microscopic analysis of different food groups were reviewed comprehensively in a book by Aguilera and Stanley in 1990 (see 'Further Reading' section). The microscopic analysis of different food commodities has been reviewed in books published in 1979 edited by Vaughan and in 1994 edited by Flint ('Further reading' section). From 1982 to 1994, the journal *Food Structure* (formerly *Food Microstructure*) specialized in the publication of papers on food microscopy and related techniques. Since 1994 there has been no journal dedicated specifically to the microscopic analysis of food, although the review journal *Trends in Food Science and Technology* carries regular articles on this subject.

## Microscopy Techniques

### Light Microscopy

Light microscopy (LM) is regularly used to obtain rapid, inexpensive qualitative and quantitative information in food analysis. The first routine use of LM in food analysis was for the identification of adulteration (e.g., the presence of chicory root in coffee) or contamination (insect, rodent, microbial, and foreign bodies). Bright-field, polarizing, and fluorescent microscopy are the three traditional LM techniques used most frequently in food analysis. The basic instrument is a conventional compound (bright-field) microscope, to which polarizing and fluorescence accessories are easily attached.

A wide variety of stains can be used in combination with bright-field LM. In food analysis, however, only a few of those stains are used on a regular basis. For example, Toluidine Blue O (TBO) is a metachromatic dye that produces different colors depending on the nature of the component to which it is bound. Pectin-containing plant cell walls stain a rich pink or purple with TBO, while lignified cells of vascular tissues stain dark blue (see **Figure 1A**). TBO is also useful for the examination of meat products, where muscle fibers show up as pale pink, fibroblasts as blue, and elastin fibers as turquoise. The familiar blue coloration produced by staining starch with iodine is widely used, allowing the identification and localization of starch even after processing has destroyed the characteristic granule structure. For fat staining, a lipid-soluble dye such as Oil Red O may be used.

Polarizing microscopy is used to examine food components that exhibit birefringence (an ordered crystalline structure). Many food components are birefringent, e.g., starch, plant cell walls, specialized 'stone cells' in some plant tissues, muscle fibers, fats from both plant and animal sources, and different types of flavor and seasoning components.

The botanical origin of most starches is readily identified on the basis of granule size and shape, the form and position of the hilum, and the

### Microscopy Techniques

#### Light Microscopy

Light microscopy (LM) is regularly used to obtain rapid, inexpensive qualitative and quantitative information in food analysis. The first routine use of LM in food analysis was for the identification of adulteration (e.g., the presence of chicory root in coffee) or contamination (insect, rodent, microbial, and foreign bodies). Bright-field, polarizing, and fluorescent microscopy are the three traditional LM techniques used most frequently in food analysis. The basic instrument is a conventional compound (bright-field) microscope, to which polarizing and fluorescence accessories are easily attached.

A wide variety of stains can be used in combination with bright-field LM. In food analysis, however, only a few of those stains are used on a regular basis. For example, Toluidine Blue O (TBO) is a metachromatic dye that produces different colors depending on the nature of the component to which it is bound. Pectin-containing plant cell walls stain a rich pink or purple with TBO, while lignified cells of vascular tissues stain dark blue (see **Figure 1A**). TBO is also useful for the examination of meat products, where muscle fibers show up as pale pink, fibroblasts as blue, and elastin fibers as turquoise. The familiar blue coloration produced by staining starch with iodine is widely used, allowing the identification and localization of starch even after processing has destroyed the characteristic granule structure. For fat staining, a lipid-soluble dye such as Oil Red O may be used.

Polarizing microscopy is used to examine food components that exhibit birefringence (an ordered crystalline structure). Many food components are birefringent, e.g., starch, plant cell walls, specialized 'stone cells' in some plant tissues, muscle fibers, fats from both plant and animal sources, and different types of flavor and seasoning components.

The botanical origin of most starches is readily identified on the basis of granule size and shape, the form and position of the hilum, and the

**Figure 1** Light microscopy of some foods of plant origin. (A) Bright-field micrographs of hand-cut section of fresh pumpkin stained with Toluidine Blue. Parenchyma cell walls, which are rich in pectin, are purple, and cell walls of vascular tissue, which are rich in phenolics, are blue. (B) Hand-cut section of fresh potato, viewed using polarizing optics. Birefringent starch granules appear bright against a dark background. (C) Fluorescence micrograph of hand-cut section of pumpkin epidermis, stained with Coriphosphine O. Bars in (A) to (C) represent 25  $\mu\text{m}$ . (D) Fluorescence micrograph showing hand-cut section of infected radish, stained with Acridine Orange (yellow fungal cells) and Methyl Green (green radish cell walls). Bar represents 100  $\mu\text{m}$ . (Miller SS, Agriculture and Agri-food Canada, Ontario, Canada.)

brilliance of the interference cross under polarized light (see **Figure 1B**). Loss of birefringence upon gelatinization, the temperature of which is characteristic for various native and derivatized starches, is determined using a polarizing microscope equipped with a heat stage. The effects of baking and processing on starches are monitored by a combination of polarizing and bright-field microscopy using iodine staining to identify starch after loss of birefringence.

Fluorescence provides a sensitivity that is not available in other forms of LM, allowing the detection of fluorescing compounds present in amounts as little as  $10^{-18}$  mol. A wide range of food components of both plant and animal origin exhibit natural fluorescence (autofluorescence). In plants, these components include pigments such as chlorophylls and carotenoids, as well as various phenolic compounds such as lignins and low-molecular-mass compounds such as ferulic and chlorogenic acids. Many flavor compounds in herbs and spices are also autofluorescent. In animal tissues, the most common sources of autofluorescence are bone, cartilage, collagen, elastin, and some lipids. In addition, fluorescence may be induced by a wide range of compounds such as fluorescent dyes, specific antibodies or lectins that are conjugated to fluorescent markers, and substances that fluoresce only in specific chemical environments. For example, Calcofluor, a fluorescent brightener, can be used as a highly specific probe to localize the mixed linkage (1 $\rightarrow$ 3), (1 $\rightarrow$ 4)- $\beta$ -D-glucan in cereal grains. Nile red is a lipid-soluble dye that becomes intensely fluorescent in the hydrophobic medium of fat droplets. The precise identification and localization of various components permitted by such compounds, coupled with the sensitivity of the fluorescence technique, has made fluorescence microscopy a valuable tool in food analysis.

Confocal microscopy has also been developed as a technique with some advantages for food analysis. The major difference between a confocal and a conventional microscope is the placement of a pin-hole at the focal plane of the image in the case of the confocal instrument. This removes out-of-focus light, generating a clearer image and allowing optical sectioning of the specimen. There are two basic types of confocal microscopy: confocal scanning tandem microscopy (CSTM) and confocal scanning laser microscopy (CSLM). CSTM uses mercury, tungsten, or xenon illuminators and has the advantage of allowing real-time observation of the specimen. Low light intensity can be a problem with this technique. CSLM uses laser illumination. Standard equipment includes an argon laser (488 and 514 nm wavelengths) with or without a

**Figure 2** Confocal laser scanning microscopy of Gouda cheese stained for protein with 1-anilino-8-naphthalene sulfonic acid. The depth resolution of optical sectioning was  $\sim 0.7 \mu\text{m}$ . (Courtesy of I. Heertje and Scanning Microscopy International.)

helium–neon laser (633 nm wavelength). In many of the CSLM systems currently in use, real-time observation is not available because of potential damage to the eye by laser emissions. Images are produced, stored, and manipulated by image-handling software. Light intensity is not a problem with this method.

CSLM can provide focused images to a depth of up to several hundred micrometers, depending on the nature of the sample, so that sequential sections may be obtained for three-dimensional reconstruction of the image (**Figure 2**). In addition, several chemical components (e.g., protein and fat in cheese) can be identified and localized simultaneously using specific fluorescent labels. CSLM has been used for the quantitative analysis of cellular structures in plant material, the structural analysis of emulsions of different complexities, and the location of microorganisms in a wide range of food products.

### Electron Microscopy

Electron microscopy (EM) is used where a higher resolution than that obtainable by LM techniques is required, for example, for the analysis of components such as casein micelles in milk or pectin fibers in fruits and vegetables, which are too small to be visualized by LM. Scanning electron microscopy (SEM) in conjunction with X-ray microanalysis, and transmission electron microscopy (TEM) in the electron energy loss spectrometry (EELS) mode, enable the analysis of foods or their components for elemental composition. SEM of frozen hydrated samples and TEM of replicas obtained from samples fixed by rapid freezing provide images of foods unaffected by chemical fixation. In contrast, chemical fixation of certain components such as proteins (using aldehydes – glutaraldehyde, formaldehyde – and  $\text{OsO}_4$ ), unsaturated fats (using  $\text{OsO}_4$  in the

**Table 1** Overview of microscopical techniques and applications in food analysis

<i>Technique</i>	<i>Mode</i>	<i>Information obtained</i>
Dissecting microscopy	Bright-field, polarizing, and fluorescence	Contamination
Light microscopy		Chemical and structural analysis
Confocal microscopy	Confocal scanning tandem microscopy (CSTM) and confocal scanning laser microscopy (CSLM)	Contamination
		Component identification
Scanning electron microscopy (SEM)	Conventional SEM	Component distribution
		Changes during processing
Energy-dispersive spectrometry (X-ray microanalysis)	Conventional SEM and cryo-SEM	3D reconstruction of low-density foods
		Structural information for food powders, solid foods, and viscous foods
Transmission electron microscopy (TEM)	Cryo-SEM	Structural information for high-fat foods and edible foams
		Chemical information
Electron energy loss spectrometry (EELS)	Conventional SEM and cryo-SEM	Chemical and structural information for liquid foods and emulsions
		Chemical and structural information for all foods
Atomic force microscopy	Thin sectioning	Chemical and structural information for liquid foods, high-fat foods
		Crystallinity
Atomic force microscopy	Freeze-fracture plus replication	Chemical information
		Very high resolution of surface structure

presence of imidazole) and some polysaccharides (using  $\text{RuO}_4$ ) followed by embedding in a resin and staining of thin sections with heavy metals such as uranyl acetate and/or lead citrate, makes it possible to distinguish these components in foods.

### Atomic Force Microscopy

Significant structural changes induced in food ingredients by processing for EM require the development of novel methods, such as environmental stages and metal-free processing, to achieve proper results. Indeed, EM techniques are pushed to their limits when they are used to image complex biopolymers such as the irregular fibrous proteins and polysaccharides that are abundant in foods. Since these types of samples have to be coated with metals, the size of the metal grains restricts the level of detail observable in the final images. Atomic force microscopy (AFM) creates an image by scanning a sharp stylus, which is attached to a flexible cantilever, across the sample surface. When the stylus is held very close to the sample, repulsive forces deflect the cantilever away from the surface. As the cantilever–stylus assembly is scanned over the surface, topological features are translated into movements, which can be recorded. This simple and highly sensitive technique can measure deflections caused even by individual molecules and atoms. It

has been widely used to study complex food components, such as protein fibrils, polysaccharides, and interfaces. Information concerning the different types of microscopy and their applications is presented in Table 1.

## Sample Preparation

### Light Microscopy

Fresh material is examined wherever possible in order to avoid artifacts (i.e., images resulting from faulty preparation) and to prevent the loss of certain components. Fresh material is also valuable where time is an important constraint, as in quality control. The examination of fresh material makes for the most rapid and straightforward analysis.

Powders are examined in their original form by dispersing them in either aqueous or nonaqueous mountants, depending on their solubility and dispersibility. The mounting media may include stains to increase the contrast of individual components for structural observation or discrimination on the basis of chemical and morphological characteristics. The detection of birefringence in powders is also useful for identification.

Smearing, squashing, and comminution are simple preparation techniques that make it possible to obtain extensive information quickly. Depending

on consistency, the product is mixed with appropriate dyes or is comminuted with a small amount of water or dye before it is spread on a slide. The sample may also be prepared for microscopy by squashing between slide and coverslip. Using these methods, appropriate dyes yield valuable chemical information on the components of the food, although the overall microstructure is generally lost.

Where information on chemical composition or structural and spatial relationships is required (e.g., comminuted meat products), the sample is sectioned before examination. The simplest and quickest procedure is to section the sample by hand using a clean razor blade, but this is possible only with rigid samples. Soft samples can be made rigid either by freezing or embedding in paraffin or a plastic resin such as glycol methacrylate. Frozen sections are produced in a relatively short time and, with the exception of ice crystals, have the advantage of few artifacts. Ice-crystal damage can be minimized by freezing the sample in nitrogen slush at  $-205^{\circ}\text{C}$  before mounting and sectioning in a cryostat. Rapid work is essential, since ice crystals grow as the sample warms up to the cryostat temperature ( $-20^{\circ}\text{C}$  to  $-25^{\circ}\text{C}$ ). Enzymatic activity in the samples is arrested at cryostat temperatures but can be observed *in situ* using appropriate chromogenic or fluorogenic substrates. With appropriate instrumentation, it is even possible to measure the rate of the reaction.

Fixation with formaldehyde or glutaraldehyde before sectioning prevents the disintegration of fragile sections on the slide when dyes or mountants are applied. The use of slides coated with albumin or poly-L-lysine to collect sections can be helpful. Some components, particularly certain polysaccharides, cannot be stabilized by fixatives, while others of low molecular mass can migrate in the sections or may be extracted from them when dyes are applied. In such cases, vapor staining can be used (e.g., starch with iodine vapor or fat with  $\text{OsO}_4$  vapor). Embedding in a resin is carried out when better resolution structural details are required. In such cases, sections  $0.5\text{--}5\text{ }\mu\text{m}$  in thickness are examined.

### Electron Microscopy

Sample preparation for EM depends on the nature of the food and the type of scanning or transmission technique used. For SEM, dry foods are prepared in the same way as powders. Solid foods based on proteins (cheese, meat) are fixed in glutaraldehyde solutions (1–3%, buffered near the pH value of the food),

dehydrated in ethanol, defatted by extraction with chloroform or *n*-hexane, returned to ethanol, frozen in liquid isopentane over liquid nitrogen or in nitrogen slush, and cryofractured. Since ethanol does not form crystals on freezing, it is possible to freeze ethanol-impregnated samples directly in liquid nitrogen. Dairy products treated in this way are known to fragment spontaneously, but this does not occur if the products are frozen in isopentane or using Freons (although the latter are discouraged due to their negative environmental impact). The fragments are returned to ethanol and critical-point dried. Dried fragments are mounted, coated with pure or alloyed gold, and examined by SEM. If fat is the food component of interest, samples fixed in glutaraldehyde are postfixed with imidazole-buffered  $\text{OsO}_4$  and the fat extraction step is omitted. Viscous samples, which would disintegrate during sample preparation, are encapsulated in agar gel. The capsules are treated in the same way as solid samples. Cryofracturing provides superior images in comparison with dry fracturing. In hydrated food samples, however, crystals may form during freezing resulting in artifacts. Only a thin surface layer ( $20\text{ }\mu\text{m}$ ) is free from such crystals.

Cryo-SEM (examination at temperatures below  $-80^{\circ}\text{C}$ ) is suitable for high-fat foods and foods of plant origin such as cooked vegetables, which could be altered by other methods involving dehydration. Rapid freezing of the samples is essential for the prevention of artifacts arising from ice-crystal formation.

Low-voltage SEM is valuable when applied to frozen uncoated samples because it allows the observation of food in the near-native (frozen hydrated) state at a high magnification, particularly by field emission SEM, which is best suited for this type of work. Since the samples do not need to be coated with metal, they may be fractured continuously over the course of the observation.

In TEM, negative staining and metal shadowing techniques are suitable for macromolecules (proteins, polysaccharides) and their assemblies (micelles). The TEM technique practiced most frequently is the examination of thin sections. In order to examine foods using this technique, small samples ( $<1\text{ mm}^3$ ) are chemically fixed and embedded in a resin such as Epon, Araldite, or Spurr's. Dense foods such as cheese, dough, comminuted meat products, seeds, and extruded products require longer fixation and impregnation times compared to porous foods. Low-viscosity resins facilitate embedding of the samples. Starch granules usually remain nonimpregnated. During sectioning, when the sections

are floated on the surface of water, they swell and expand. Subsequent drying results in the development of folds in the granules. These result in artifacts (dark, star-like areas in the micrographs). Separate protocols have been developed for most foods.

Freeze-fracturing, freeze-etching, and replication with platinum and carbon, followed by TEM of replicates is the technique most often used for the examination of high-fat dairy products such as cream, oil-in-water emulsions such as ice cream, and water-in-oil emulsions such as margarines and low-fat spreads. Micrographs obtained by any kind of microscopy, which used to be recorded on film, are now recorded as digitized images and may be manipulated using computers and software, which come as part of the EM setup.

## Applications

### Contamination of Food

One of the most important applications of food microscopy is the detection and identification of contaminants in food, usually following a consumer complaint. Macroscopic examination is followed by examination under a binocular dissecting microscope. Foreign bodies, such as metal, rubber/plastic, glass, wood, and crystalline solids may be identified at this stage, as also some biological contaminants (e.g., animal or insect parts). Biological contaminants of microbial origin may not be detected at this stage, unless they have formed colonies. Some foreign bodies may occur in finished food because of crystallization (e.g., tyrosine crystals in anchovy paste) or interactions between components (e.g., calcium oxalate crystals in foods containing milk and vegetable constituents). Sometimes food is unintentionally contaminated while being processed in the kitchen (e.g., by glass or enamel particles from kitchen utensils) or even during consumption (e.g., by chips of tooth enamel or fillings). Many of the more difficult cases of food contamination can now be solved with the aid of elemental X-ray microanalysis and using procedures compiled by Lewis (see 'Further Reading' section).

### Structural Analysis

Food microstructure is intimately related to its sensory properties, e.g., elasticity, firmness, smoothness, and juiciness. Proteins and carbohydrates form gels, the structures of which affect water- and fat-retention properties. Gel structures of various biopolymers (e.g., gluten, myosin, starch, glycogen) have been studied extensively. Fats and oils,

their crystalline forms, emulsions, and foams, represent another important area of food structure studies in which all kinds of microscopy are used. Findings from traditional foods may be applied to newly formulated foods to improve their consumer appeal.

### Dairy Products

Most dairy products, including yogurts and cheeses, are based on casein micelles (protein globules  $\sim 100$  nm in diameter) and whey proteins. Casein micelles and coagulated whey proteins must be examined by EM because LM techniques do not provide sufficient resolution.

Coagulation of milk results in two different kinds of gel, depending on whether the milk has previously been heated above  $85^{\circ}\text{C}$ . Heating leads to interactions between  $\kappa$ -casein on casein micelle surfaces and a whey protein called  $\beta$ -lactoglobulin. The resulting protein complex occupies sites suitable for interactions with the micelles, and the gel consists of short interlinked chains and minute pores in which the liquid phase is firmly immobilized. This structure retains the liquid phase and is important for soft milk products such as yogurt. Large protein clusters develop in coagula made from unheated milk, and result in syneresis of the gel, i.e., separation of the liquid phase called whey. These structures are important in cheese-making.

Identification of specific food components such as proteins and polysaccharides is possible by immunolocalization using gold-labeled antibodies (Figure 3). In conjunction with X-ray microanalysis, SEM is used to analyze salt crystals in cheeses, including

**Figure 3** Immunogold labeling of egg albumin (minute black dots) which forms a wrapping layer around casein micelles (arrows) in microparticulated protein. The bar represents  $0.5\mu\text{m}$ . (Reproduced from Singer and Dunn (1990) by N.S. Singer and John Wiley & Sons, Inc.; © 1990 Wiley.)

**Figure 4** Results of SEM-EDX analysis showing distribution of (a) calcium and (b) phosphorus at Camembert cheese surface (c) in the mass of mold hyphae M; C image of a freeze-fractured Camembert cheese surface showing the protein matrix C and the hyphae M. (Micrographs (a) and (b) reproduced by courtesy of B.E. Brooker and Scanning Microscopy International.)

deposits of the surface of mold-ripened cheeses such as Camembert. Metabolic activity inside the dense hyphal mat at the cheese surface increases the pH of the cheese and leads to the precipitation of calcium and phosphate ions present in the cheese (**Figure 4**). This process may continue until most of the ions diffuse out of the cheese interior and form a deposit at the cheese surface.

Cryo-SEM or TEM examination of platinum-and-carbon replicas of whipped cream shows stabilization of the air cells by fat globules that adhere to the air-liquid interface. Distribution of intact fat globules and water droplets in butter and other emulsions is also conveniently studied by these methods in which the sample is fixed by rapid freezing.

## Meats

The basic component of meat is muscle tissue, which has a complex microstructure. Individual myofibers are surrounded by connective tissue membranes (endomysium) and bundles of myofibers are separated from each other by another connective tissue membrane, the perimysium. Muscle also contains veins, arteries, and nerve fibers. Skeletal (or striated) muscle differs in microstructure from the smooth muscle that is present in internal organs such as

intestinal walls, blood vessels, etc. Microscopy is used to analyze changes that occur in muscle structures after the animal has been slaughtered, during so-called rigor mortis and then during ageing, freezing, salting, and processing of the meat. These processes cause changes to the muscle microstructure, but the most significant changes are caused by heating, which denatures proteins, leads to shrinkage of the muscle fibers, and the loss of fine structure. Such changes can be observed by LM and EM techniques. Individual components in raw meat, meat heated to over 80°C, and cooked meat can be detected using specific antibodies to native and denatured meat antigens in combination with quantitative fluorescent microscopy.

Comminuted meat products consist of several components and are usually referred to as meat emulsions. The binding of meat and fat particles is improved by the use of fillers, which consist of soy or grain flours, sodium caseinate, starch, gluten, and other polysaccharides and proteins. Their role is to increase yield, improve stability, and modify textural properties. Microscopy is used to detect the presence of fillers, determine the quantity, and establish their distribution.

## Foods of Plant Origin

This group of foods is diverse, encompassing grain flours, dough, bakery products, products derived from starch and/or vegetable proteins, fruits, and vegetables. The consistency of these foods ranges from liquid (fruit and vegetable juices, beer, wine) through moist foods (bread, baked potatoes, tofu) to low-moisture products (potato crisps, bread-crumbs). All these products are derived from plant cells, the walls of which consist of cellulose, hemicelluloses, lignin, pectins, and proteins. The structure and composition of plant cells as foods is discussed in detail by Aguilera and Stanley (see 'Further Reading' section). Foods of plant origin are often prepared by cooking and/or freezing and are amenable to analysis by LM and EM techniques. In contrast, extruded foods are produced by a complex process in which high temperature (100–200°C), high pressure (2–6 MPa), and mechanical shear are applied to the food. The resulting porous as well as compact samples are difficult to embed in resin and to section for LM and TEM. Therefore, SEM is the technique most frequently used to analyze this category of food.

Compared to meat and dairy products, many plant foods contain little or no protein. Starch cannot be fixed by chemical methods, therefore, EM methods involving freeze-fractured samples yield the best results.

## Trends in the Microscopic Analysis of Foods

Over the last few years, there have been significant advances in the analysis of food structures at the microscopic level. These advances have been brought about in part by the development of new techniques and their application to traditional problems, but the inclusion of image analysis as an essential component of quantitative food analysis has also played an important role. Two of the most important developments are the increasing use of AFM and confocal laser scanning microscopy in the analysis of food microstructure. For example, AFM has been used to investigate the structure of fats and oils, and has provided convincing evidence for the presence of microcrystal networks within such substances. This was possible thanks to a recent innovation in AFM technology, known as the tapping mode, in which the cantilever connected to the stylus is oscillated as it scans the sample surface, allowing AFM to be used with soft and hydrated food materials. Another example is the use of CLSM to study the impact of oil frying on potato slices. The ability to generate non-destructive optical sections of the sample facilitated the detection of oil penetration into the crust, followed by three-dimensional reconstructions that showed the oil forming around the cells and penetrating the food through intercellular spaces, while almost no oil was seen in the cells themselves. It is likely that these two key techniques will complement LM and EM methods and play an increasingly important role in food structural analysis in the future.

## Introduction

The field of forensic microscopy is based upon Edmond Locard's Exchange Principle, which states that when two objects come into contact, a transfer of material will result. Although the amount of material that is transferred in a contact may be minute, microscopical examination can often reveal a great amount of information regarding the materials that came into contact and the way in which they made contact. This article illustrates the way in which forensic microscopy can capitalize on this transfer of

material to aid in establishing the facts within a criminal investigation, describe the types of problems that are addressed, the types of materials encountered, and the analytical approach used to extract information from trace evidence. Finally, a practical example that illustrates the extent to which microscopic evidence can influence the outcome of a case will be described.

## The Role of Forensic Microscopy

The field of forensic microscopy is quite broad in that it deals with any possible type of microscopic residue, which may have biological, geological, or anthropogenic origins. For example, in sorting through the material encountered on a single pair of pants

recovered from a victim at a crime scene, the microscopist may encounter: soil and pollen from environments to which the victim has been exposed; fibers from clothing, carpeting, or automobiles; biological stains (e.g., blood or semen); hair from the victim and/or suspect; or animal hair. In addition, the victim may have picked up materials more characteristic of a specific anthropogenic environment such as paint, asphalt, glass, wood, metal. These are only a few of the many types of materials that may be encountered, and it is the job of a forensic microscopist to (1) determine the identity of these materials, (2) determine which may have potential value as forensic evidence, and, in some cases (3) establish the significance of the potential evidence in the context of the case. For this reason, a forensic microscopist must possess both a broad general knowledge of materials and a detailed knowledge of the specific microscopic characteristics of these materials so as to be able to classify, if not outright identify the materials encountered as specifically as possible.

Forensic examinations generally progress toward one of two ends: comparison or investigation (i.e., intelligence). Comparative cases are the norm and involve the comparison of suspect material to materials of known origin. In these cases, the goal is to link a suspect to victim or vice versa. An example would be a microscopical comparison between hairs found on a victim to a reference hair sample collected by investigators from a suspect. The less common, and more difficult, investigation involves cases in which police have no suspect and are attempting to establish investigative leads. In these cases, the goal of forensic microscopy is to study microscopic trace evidence to provide police with characteristics of the suspect and/or the type of environment upon which to focus their efforts. In these cases, the forensic microscopist must extract as much information as possible from the trace evidence recovered from a victim. An example of this type of investigation would be a hit-and-run collision in which paint is transferred from the offender's vehicle to the victim. These microscopic chips of transferred paint (Figure 1) can be recovered and studied in terms of the structure of paint layers, color, and chemistry to determine the make, model, year, and color of the involved vehicle. The police can use this information to narrow their search to a particular type of vehicle.

While forensic microscopy is most often considered in regard to the prosecution of a criminal case, microscopic evidence can also be used to advantage by the defense, or even within the realm of civil litigation. Additionally, while this article presents forensic microscopy as an independent topic, the reader must keep in mind that microscopic trace

**Figure 1** Cross-section of a chip of automotive paint. Microscopic examination of the layers and layer thickness, color of each layer, and chemistry of the paint in each layer can be traced back to a specific paint manufacturer and possibly even make, model, and vehicle year. (Courtesy C. Palenik.)

evidence is often used in conjunction with, or is supplemented by, other types of physical evidence (e.g., DNA, fingerprints).

## Materials Encountered

As mentioned above, microscopic evidence spans a vast range of materials (see Table 1). Some material can be easily recognized as hair, a fiber, or soil. Other material, such as biological stains, residues, and white powders, are not immediately recognizable. Take, for example, the recent need to identify anthrax spores and the macroscopic similarity they pose to other common white powders such as wheat flour, starch, or other less dangerous bacteria. In general, materials that cannot be identified by sight are classified and subclassified on the basis of their physical properties. A preliminary microscopic investigation of trace evidence is generally sufficient to classify a material's origin as biological, geological, or anthropogenic. Further classification of a particular sample, or particle, can be made more specific by using morphological characteristics and, if necessary, additional analytical methods to provide more detailed information. For example, even a material such as glass (a transparent, isotropic, conchoidally fractured solid), which can be quickly identified on the basis of morphology and a preliminary examination of optical properties, can be further examined to provide a precise determination of refractive index and trace elemental composition, which will aid in determination of the source of the glass. The procedures by which samples are characterized are dependent on the sample as well as the requirements of a particular investigation (for more information, see

**Table 1** Example of the variety of trace evidence that may encountered in a microscopic examination

<i>Category</i>	<i>Class</i>	<i>Subclass</i>
Biological	Pollen	
	Vegetable fibers	Cordage, fabrics, clothing
	Seeds	
	Hair	Human, animal
	Diatoms	
Geological	Wood	Hardwood, softwood
	Soil	
	Sand	
Anthropogenic	Metals	
	Polymers	Fibers (auto, home, clothing) Paint (auto, home) Plastic
	Industrial	Chemicals, pigments, explosives
	Pharmaceutical	Drugs, herbal supplements
	Paper	Paper fibers
	Glass	Window, bottle, windshield, light bulb
	Food	Flour, starch, prepared foods

the next section ‘Techniques’). The remainder of this section will briefly discuss some of the more commonly encountered microscopic evidence and a survey of the potential information that microscopical study may provide.

### Geological Materials

Geological materials include soils, sand, and dust. These substances are commonly recovered from the clothing and shoes of suspects and victims; tires, wheel-wells, and floor mats of vehicles; and from the scene of a crime. The amount of material available for microscopic analysis can vary from several pounds of material accumulated on a vehicle to microscopic amounts of soil vacuumed from the clothing of a victim. These materials can be used for comparative purposes, to demonstrate a suspect or victim has been present at a particular site, or they may aid in establishing investigative leads in cases where no suspect exists. In the first case, soil from a suspected location is compared to a number of known samples from various locations collected by investigators. Although each case is different, a typical examination would begin with a comparison of color and particle size between suspect and known samples. The examination would continue with an examination by polarized light microscopy to identify the mineralogical composition of the suspect soil,

which can then be compared to the minerals identified in known soils. In investigative cases, the police are looking for leads, so soil recovered from a victim may be examined for the purpose of establishing the environment of the location at which the victim picked up this material. Every environment has a characteristic, though not necessarily unique, composition of soil. A forest’s soil will be rich in organic matter; a desert soil will have virtually no organic matter, but may contain characteristic salts. On a regional scale, the type of rock from which the soil originates (igneous, metamorphic, or sedimentary) can be determined from a soil’s mineralogy and may help to define or differentiate specific locations. In addition to purely geological materials, soil often contains other materials such as concrete, asphalt, or pollen, which can be used in conjunction with the geological components to make a comparison or investigative lead stronger or more helpful.

### Biological Materials

The most commonly encountered biological materials in microscopical examinations include hair and fur, pollen, diatoms, wood, vegetable fibers, and residues, such as blood, food, and semen. The solid materials in this list are identified primarily on the basis of morphology, while residues are most easily identified by specific microchemical tests. Similar to geological materials, biological materials can serve to provide an investigative lead, or aid in comparative examinations.

The microscopical identification and examination of hairs can be treated as an independent examination, or can be used in conjunction with DNA analysis. In addition to human hairs, animal hairs can also play a significant role in criminal investigations. The hair of an animal species (human, cat, dog, etc.), as well as the location from which a hair originated (head, limb, pubic, etc.), can normally be identified by morphological characteristics of the cuticle, cortex, and medulla (shown in **Figure 2**). In human hair, various morphological tests such as pigmentation, thickness, and the amount of curl can be suggestive of race. In animal hair, these characteristics can aid to distinguish among species of a particular type of animal, such as the breed of a dog. In addition to these natural comparative features, examination of the root can provide evidence as to the way in which the hair was removed (i.e., forcibly removed, shedded, cut, etc.) and whether the hair was removed postmortem. The tip of a head hair can provide evidence as to relative time of the last haircut and how the hair was cut (i.e., with scissors or a razor). Additionally, hair treatments, such as dying

**Figure 2** Structure of an animal hair. The morphology of the cuticle, cortex, and medulla along with other features such as pigmentation, inclusions, and thickness can aid in the identification of the hair species. (Courtesy S. Palenik.)

or the addition of styling products, can be identified or extracted for further examination. The identification of such characteristics makes a hair more unique, and thus more useful in a microchemical or instrumental examination.

Pollen grains are the male gametophytes of seed-bearing plants. They are produced and released at specific times of the year. This predictable dispersal, coupled with the fact that plants grow in well-defined ecological niches, makes them useful as environmental indicators and, therefore, pollen also serves as an excellent location indicator. In some cases, this information may be as general as to suggest that a victim has been struggling in a field of dandelions, or as specific as to suggest that police seek an indoor greenhouse that contains a rare type of flowering plant not common to the continent.

Diatoms are the siliceous skeletons of certain algae. These may be derived directly from an aqueous source, but may also be found in diatomaceous earth. Commercial uses for diatoms include safe insulation (usually older safes), as mild abrasives, filters, or as a filler in concrete, plastics, paint, and paper. They may also be encountered in certain types of soil samples. The presence (or absence) of diatoms, the number of diatoms, and the species of diatom can all provide useful information.

Wood may be encountered in a variety of forms including: recognizable pieces, splinters, environmental dust, tool dust, or as filler in polymers or paper fibers. Both the species and the end-use of a wood sample can aid in comparative and investigative examinations. Even small slivers of wood can be classified into a proper subdivision as an angiosperm (hardwood) or gymnosperm (softwood) based on fundamental microscopic structural differences.

Identification to the species level may be completed if the sample is large enough to permit observation of other morphological identifiers. Wood that has been treated for industrial uses, such as paper, can be identified as such microscopically. Further microchemical tests can be applied to paper-making fibers to establish the end-use of the paper (i.e., newsprint versus stationery).

Vegetable fibers include materials such as sisal, silk, and cotton, to name a few, which are used in clothing, cordage, carpet backing, or for packing (e.g., jute). Microscopically, these materials can be distinguished from synthetic fibers and further classified on the basis of their microscopic plant anatomy.

### Anthropogenic Materials

Anthropogenic materials encompass the most commonly exploited class of microscopic trace evidence, because the evidentiary significance of a unique anthropogenic material can often be more specific than a biological or geological indicator. As shown in **Table 1**, anthropogenic materials encountered as microscopic evidence include every conceivable material including synthetic and regenerated fibers, paint, glass, concrete, ceramics, metals, plastics, chemicals, drugs, and soot, to name but a few.

The transfer of synthetic fibers from victim to suspect represents one of the most useful types of trace evidence, due to the large amount of information that can be extracted from a single fiber. Useful indicators include the generic class of the fiber (e.g., nylon, polyester, etc.), color (dyed or pigmented), the optical properties (e.g., refractive indices, birefringence), melting point, cross-section, and inclusions, all of which can be quantitatively measured by currently available microscopical, microchemical, and instrumental techniques. Using this information, a single fiber can provide information as to the potential end-use of the fiber (e.g., residential, vehicle, industrial) and, in some cases, even the manufacturer and trade name of fiber. The latter information can increase the evidentiary significance of a fiber by providing a source for information about the availability of a fiber in a particular market. A rare fiber will be potentially more significant than a commonly encountered type of fiber.

Paint evidence is most commonly encountered with regard to automotive paints due to the frequency of transfer in cases involving collisions with automobiles. However, paint recovered from other settings can also provide a wealth of information (see the case description in the final section of this article). **Figure 1** shows a cross-sectional image of

the layers of paint coating an automobile. Each layer in an automotive paint serves a different purpose: the primer layer enables paint to bond to the auto body, the top coat provides the vehicle color, and the clear coat provides ultraviolet and scratch protection to the surface of the car. Each layer, as well as the combination of layers, can aid in the comparison of two paint samples, or in determining the make and model from which an unknown paint chip originated. Within the top coat, or colored layer, the composition of the polymer can be determined by infrared microspectroscopy, which will provide information as to whether the paint is original or repaired. Additionally, the paint color can be quantitatively measured; and the pigments used and their relative proportions can be identified. In the clear coat layer, the polymer used can be identified. Furthermore, the effectiveness of the clear coat layer to protect the colored layer below from ultraviolet (UV) light degrades with time by exposure to the sun. The UV absorption properties of the clear coat layer can provide information about the relative amount of weathering experienced by the paint, which can be characterized by UV-visible microspectrophotometry. Laboratories such as the Bundeskriminalamt in Germany maintain extensive physical collections representing thousands of samples of automotive paint and corresponding chemical analyses. This information is organized in a searchable computer database accessible to laboratories across the nation to assist in quickly identifying the vehicle involved in a hit-and-run case.

Glass is another commonly encountered material in forensic cases. Most glass examinations are undertaken for the purpose of comparison. In some cases, it is more useful to know the source or possible end-use. This can be determined from the refractive index, strain, surface morphology, size, and glass composition (major and trace elements). Common sources of glass include windshields, turn signals and headlight housings, auto-lamp bulbs, household bulbs, windows, drinking glasses, bottles, etc. Each type of glass has characteristic chemical and physical properties. In the case of a comparison between two fragments of glass suspected to be from the same original piece, trace element analysis can be used as a fingerprinting technique to compare the composition of minor elements. In source determinations, the topography of original surfaces as revealed by interference microscopy can be of special value.

As mentioned in the introduction to this section, white powders obtained in small quantities are often among the most difficult materials to identify solely on the basis of morphology. These can include virtually any transparent, colorless solid (organic or

inorganic) and include materials such as salts, chemicals, food products, fertilizers, and explosives. Although some of these materials, such as drugs, are routinely processed by other sections of a crime laboratory (i.e., narcotics), all of these may, from time to time, be extracted or collected in small quantities in a microscopic examination of trace evidence. In these cases, chemical microscopy combined with the measurements of optical properties is typically the best way to approach their identification (see discussion in the techniques section of this article). Additionally, analytical methods such as various spectroscopies can be used to further characterize or identify these substances.

Industrial products such as asphalt, concrete, ceramics, and metals can often provide information about a specific environment or industrial process. In addition to identification of the material, the morphology and surface striations can provide further information, such as the type of tool that produces a metal particle of a particular morphology (e.g., welding spheres produced by an arc-welder, or brass turnings produced by milling of brass).

Finally, microscopic particles that comprise soot and dust can suggest a particular environment. This soot or dust may be collected as residue from a surface, or even from an ear or a nose. Regardless, the soot and dust of many manufacturing processes can be distinguished on the basis of the composition and morphology of the material, or in the case of soot, by the residue of any incompletely combusted material.

## Techniques

The general trends in forensic science are tending toward standardized operating procedures and protocols of analysis. Due to the variety of materials encountered and the wide range of analytical techniques available to characterize samples (as will be discussed in this section), a standardized set of procedure for analysis in forensic microscopy cannot exist as rigorously as in other types of analyses (e.g., narcotics, DNA). The nature of the analysis is highly dependent upon the type of sample, the amount of sample, and the questions that are being investigated. This, in turn, dictates the path of the analysis and the analytical techniques that are applied. For simplicity, this section will discuss the general approach that is followed in a typical microscopical examination. A complimentary discussion of many of these techniques is found elsewhere.

### Sample Collection, Isolation, and Preparation

Samples can be recovered from a variety of sources including clothing, skin, carpeting, and vehicles, to

name but a few. To recover trace evidence, which often occur as only dust or even as a single particle, a variety of techniques have been developed. These include: ‘scraping’, the least elegant technique where material is roughly knocked off of an item of evidence onto a fresh surface where the loose material can be collected; ‘hand picking’, where specific particles removed by means of forceps, needles, or magnets are transferred to a microscope slide or Petri dish; adhesive tape, which, when applied to a surface such as fabric, will lift loose particles from a surface; a vacuum filter, whereby a vacuum pulls particles from the surface of evidence, which are then concentrated on a membrane filter in the path of the vacuum line; and extraction, where soluble residues are dissolved from a piece of evidence and the solvent evaporated.

Once collected, the material concentrated on a microscope slide, adhesive tape, or filter is examined under a low-power stereomicroscope. **Figure 3A** shows a low-magnification photomicrograph of sand taken with a stereomicroscope (**Figure 3B**). Using a stereomicroscope, the forensic microscopist can characterize the heterogeneity of a sample and carry out a preliminary classification to determine the next analytical step. The stereomicroscope also serves as an aid when manipulating and isolating particles for other techniques.

Sample manipulation is typically carried out under the microscope using a sharpened tungsten needle. The manipulation of individual particles as small as a few micrometers in diameter can be carried out with relative ease after training and practice. In addition, microscopic specimens often need to be divided to preserve material for additional analyses, or cut into thin sections to observe a material such as wood or a fiber from a particular orientation. While a microtome can produce extremely thin and uniform sections, a skilled microscopist can cut free-hand thin-sections, suitable for most microscopic analyses, under the stereomicroscope using a razor blade much more quickly than a microtome.

During an examination under the stereomicroscope, particles of particular interest are isolated and mounted for examination by polarized light microscopy, typically the next step in a forensic microscopical examination. By this point, the microscopist typically has a good idea of the material being observed, or at least the class of material, which aids in the choice of method for mounting the particle for additional analyses.

### Advanced Analytical Examination

Typically, the next step is examination using the polarized light microscope (PLM). The PLM (**Figure 4A**) is a compound microscope fitted with two

polarizers. Using polarized light microscopy, the optical properties (e.g., refractive index, birefringence) of a transparent solid compound can be observed and measured. These properties have been tabulated for the most common organic and inorganic compounds and can be used to identify an unknown material.

**Figure 4B** is a photomicrograph of a cross-section of a trilobal nylon carpet fiber photographed in plane polarized light. The geometry of the cross-section is a characteristic that can provide information about the manufacturer and end-use of the carpeting.

Microchemical analysis, a branch of microchemistry, is based on the performance of chemical reactions using single particles and microliters of solution

**Figure 5** Microchemical test for an aldehyde. The two capillary tubes indicate the positive (colored) and negative (colorless) results for this test. Each capillary contains  $\sim 100\ \mu\text{l}$  of solution, indicating the scale at which these reactions can be carried out. (Courtesy S. Palenik.)

to identify functional groups, ions, or compounds. Typically, microchemical reactions are carried out in capillary tubes, on microscope slides, or on filter paper. Developed before the other analytical techniques mentioned below were invented, microchemistry remains a rapid, accurate, and extremely sensitive means by which ions, functional groups, and compounds can be identified. The microchemical test for an aldehyde using Schiff's reagent is illustrated in **Figure 5**. Both capillary tubes in the figure contain  $\sim 100\ \mu\text{l}$  of solution. The lower tube is a blank, illustrating the negative test result. The upper capillary tube has become red upon reaction with Schiff's reagent, and indicates the presence of the aldehyde group in the sample. The scale upon which these reactions can be carried out allows for the detection of picogram quantities of materials.

The scanning electron microscope (SEM) coupled with an energy dispersive X-ray spectrometer (**Figure 6A**) can be used to study materials at magnifications that far exceed the maximum of the light microscope, and, sometimes, most importantly, provide elemental analysis of materials. **Figure 6B** shows a photomicrograph of a quartz grain collected with the SEM. The surface features of the grain shown in **Figure 6B** can be studied in considerably greater detail than is possible with a PLM due to the higher resolution of the SEM. In this grain, sharp, fresh fracture surfaces are visible, suggesting that this grain is freshly broken from its host rock. This grain was deposited by a glacier. Morphological details such as these can be exploited when comparing samples or searching for investigative leads. In addition to imaging, the energy dispersive X-ray spectrometer is capable of

qualitatively identifying the elemental composition of a material.

Other useful microscopic analytical techniques include hot stage, fluorescence, and cathodoluminescence microscopies; micro-infrared spectroscopy; micro-Raman spectroscopy; ultraviolet-visible microspectrophotometry; and X-ray diffraction; however, the discussion of these techniques is beyond the scope of this article. Briefly stated, each of these techniques can be used to ascertain additional information about characteristic properties of a material. The microscopist must be aware of all of these techniques, and others, so as to be able to extract the necessary information from a sample when the need arises.

## Application of Scientific Results to Forensic Casework

Many routine analyses of evidence are carried out in forensic science, with DNA, fingerprints, and drug analysis. The cost associated with microscopical examinations relative to some of these more routine analyses, along with the expertise required of a forensic microscopist, and, finally, the lack of understanding as to the amount of information that can be provided by even a preliminary microscopic examination has limited the number of cases to which the techniques discussed in this article are applied. As a result, the power of this field is often reserved until an investigation is well advanced, a case is considered to be 'high profile', or an investigation has reached a dead end. A prime example of a case in which forensic microscopy played a key role was the Green River serial murders in the Seattle, WA area, which stretched over more than 15 years.

Beginning in 1982, police in Washington began to find bodies of murdered women who all fit a similar profile. These murders continued for nearly 20 years as murders attributed to a single murderer began to accumulate until the total exceeded 40 people. Twice during this time, police made inquiries into a suspect, Gary Ridgway; however, they had no specific evidence linking him to the crimes and he could never be charged. In 2001, DNA evidence recovered from the bodies of four victims linked Ridgway to the murders. While DNA evidence proved Ridgway had been with the women, it did not prove Ridgway was the murderer, and Ridgway planned to plead innocent and fight the charges in court.

Looking for more evidence, investigators requested a microscopic review of the victims clothing for trace evidence. When examined, similar types of microscopic particles of spray paint were identified on several of the victims. Using light microscopy, electron microscopy, and micro-infrared spectroscopy, the paint manufacturer was determined. The formulation turned out to be a rare type of paint, used in only in small quantities, mainly by repaint shops and detailers. Ridgway was a painter and detailer in a large truck manufacturing facility in the Seattle area that used this specific type of paint as an original finish.

The paint particles were picked up by Ridgway at work, embedded in his clothing and car, and then transferred to anyone else in contact with Ridgway or his vehicle. The paint provided a direct link between Ridgway and several of the murdered women, as well as a link between the women. As a result of this new evidence, Ridgway was charged with three

new counts of murder. Soon after, he agreed to a plea bargain and plead guilty to 48 counts of murder, the most ever by a single person in the United States, in exchange for avoiding a death sentence.

This case example serves to illustrate several points: first, that forensic microscopy should be applied as an early line of examination rather than a late one. The above case is a prime example of an examination in which an investigative, rather than comparative, approach may have likely led to an earlier resolution of a serial murder case. Second, the scientific approach pursued in each case involving the microscopic examination of trace evidence may be different. Thus, the forensic microscopist must be a true scientist who is able to adapt the techniques and methods available to the requirements of the case at hand and not be bound to a standardized procedure devised for the use of technicians.

## Brief History

The invention of electron microscopy dates back to 1931 and is credited to Ruska, who succeeded in identifying small biological objects with a transmission electron microscope (TEM) operated at low voltage (50 kV) and exhibiting a resolution far beyond that of photon microscopy. Eventually, Ruska was awarded the 1986 Nobel Prize for his fundamental work in electron optics, shared with Binnig and Rohrer for their invention of the scanning tunneling microscope in the late 1970s.

The developments in lenses and specimen preparation took almost a decade since the invention prior to the first publications on the use of electron microscopy and interpretation of micrographs for the investigation of environmental samples. The

establishment of the earliest scanning-transmission electron microscopes (STEMs) in the late 1930s, the first scanning electron microscope (SEM) in the early 1950s, followed by the development of high-voltage microscopes, the incorporation of different detectors (energy-dispersive X-ray spectroscopy, EDS; electron energy loss spectroscopy, EELS), and the development of brighter electron sources (LaB<sub>6</sub>; field emission guns, FEGs) in the 1960s and 1970s opened increasingly new opportunities for the study and the analysis of a broad range of environmental specimens with various thicknesses and compositions. The emergence of environmental scanning electron microscopes (ESEMs) in the late 1980s dramatically completes the palette of instruments amenable to the study of samples from the environment.

The earliest observation of soil particles by electron microscopy dates back to 1940, when a preparation scheme for the identification of airborne particles at magnifications up to 200 000× was initially published in 1946. It was, however, not until the mid-1970s that the first papers dealing with suspended aquatic particulates finally appeared. Since then more than a 1000 publications have been reported to link the use of electron microscopies to environmental particles and colloids. Historically, electron microscopies have been exploited for the evidencing

<sup>†</sup>Dr. Denis Mavrocordatos is deceased. He tragically disappeared on Lake Geneva on 6 December 2003. "Homme libre, toujours tu chériras la mer!" (Charles Baudelaire).

of the morphotypes, textures, and sizes of particulate materials in environmental samples, and the majority of micrographs published had been used until recently for merely illustrative purposes. Nowadays, analytical electron microscopies have emerged from their infancy in the broad field of environmental science, and are used frequently in order to demonstrate and quantify the presence of well-characterized species down to the nanometer scale, or even to assess relationships between the formation or existence of specific types of particles or colloids at the microscopic scale, and the functioning of their natural milieu at the macroscopic scale. Indeed, this article focuses on the specimen preparation methods dedicated to scanning and transmission microscopies, and to the extraordinary potentialities of the latter for solving environmental situations and processes involving complex and heterogeneous species.

## Sampling and Specimen Preparation

Unbiased electron microscopic investigation of particulate material, be it of living (bacteria, protozoa, algae, cellular fragments) or nonliving nature (macromolecular organics, viruses, crystalline or amorphous mineral phases), requires a blend of dedicated sample collection schemes and specimen preparation techniques. **Figure 1** serves as a rough guideline for the selection of the most adequate microscopic approach, from specimen preparation to particle characterization.

Whatever the investigation to be performed on whichever sample, it must be kept in mind that every step of the protocol should be designed to avoid modifications of the native physicochemical characteristics of the sample (e.g., precipitation/coagulation/dissolution due to shifts in particle concentration, ionic strength, pH, redox potential, temperature or uncontrolled dehydration of sample).

### Aerosols and Atmospheric Particles

Atmospheric particles are probably the most straightforward to sample, as a variety of collectors have been devised and optimized for more than half a century, in which particulate material can eventually be size fractionated as a function of the operating conditions of the collector. As opposed to aquatic systems, sampling of particles in a gaseous milieu is less sensitive to physicochemical changes, although biased size fractionation may occur due to particle hydrophilicity/hydrophobicity or surface charges (this should be concurrently checked by scanning mobility particle sizing).

For indoor particles (e.g., asbestos fibers, industrial particles, soot, or combustion smoke of health concern), direct sampling by air pumping through

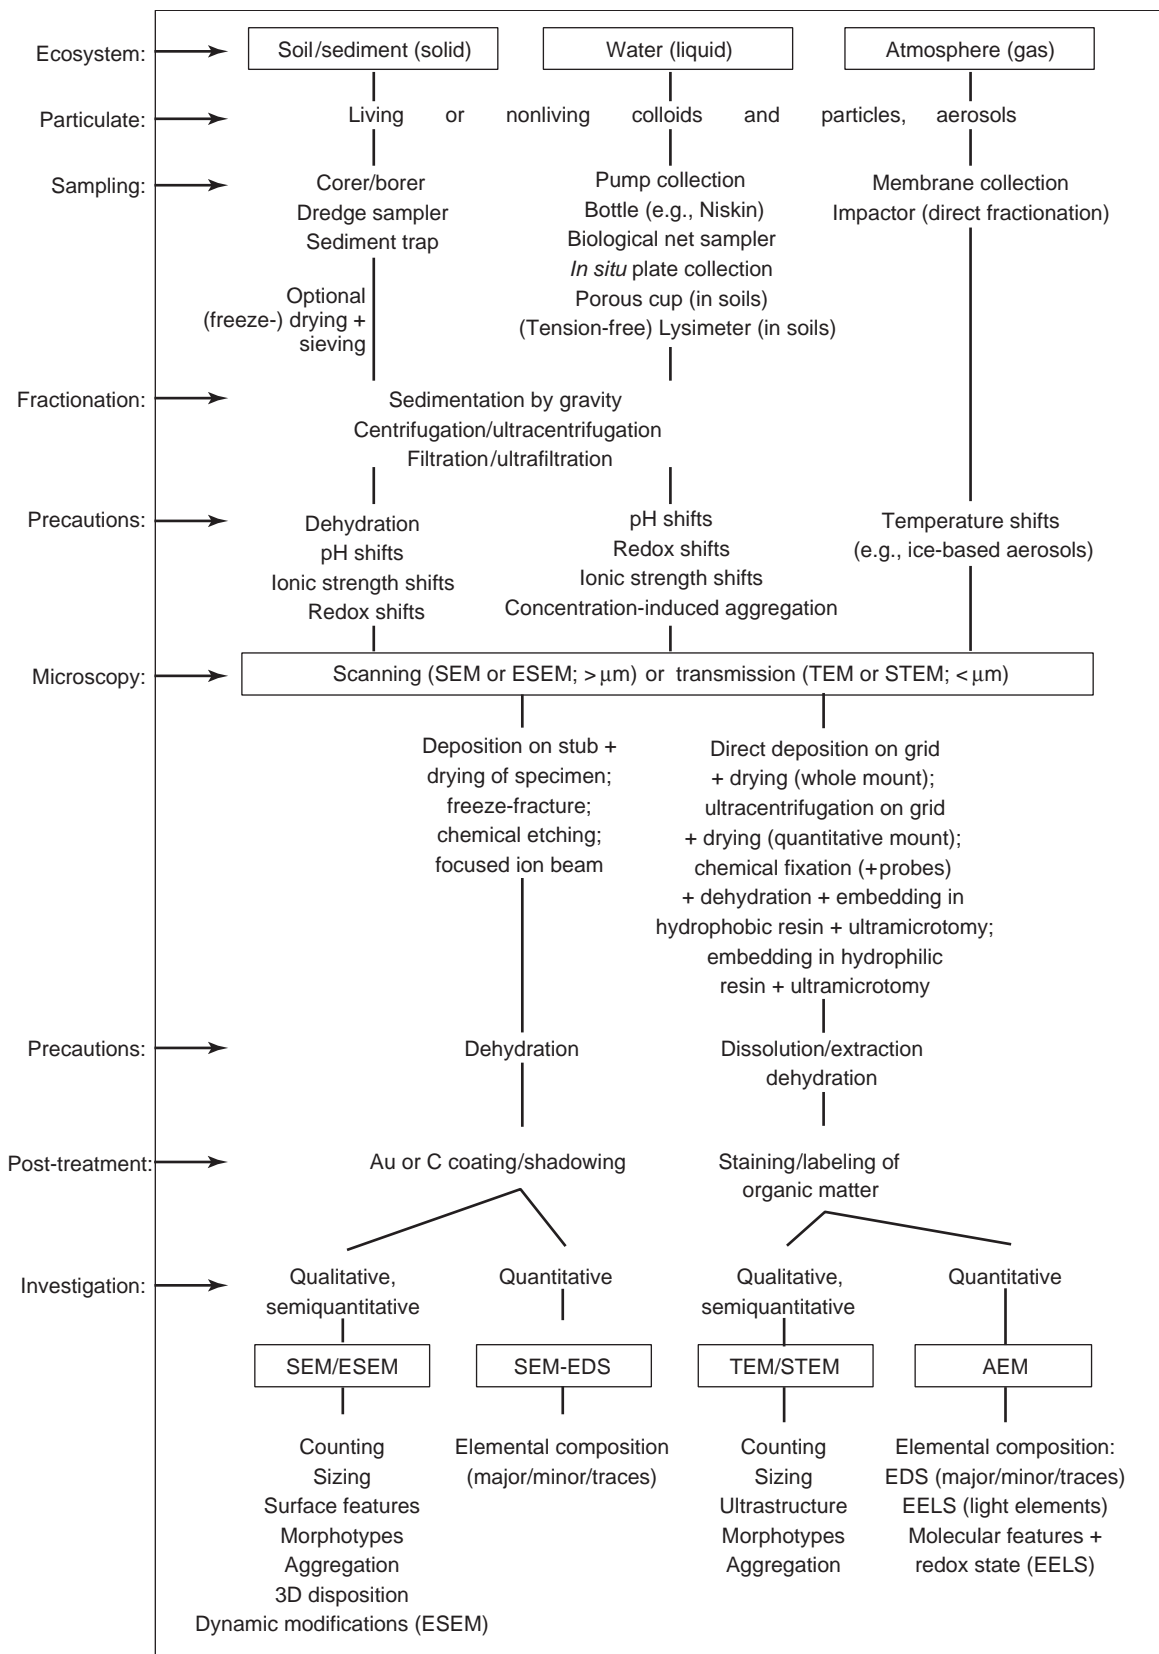

collecting membranes (smooth/flat neutron-impacted Nuclepore<sup>TM</sup>-type filters) without size fractionation is best suited. Outdoor atmospheric or plume particles can be size fractionated and collected by cascade impactors, charged-particle collectors, thermal precipitators, or nephelometers. Particles will have to be transferred by contact from the sampling device to the specimen holder, be it a stub for SEM or a grid for TEM.

The collection of aerosols requires special procedures aimed at maintaining the original temperature and hydration status of the sample, in particular for studies involving wet or iced entities in which the mechanisms of cloud or ice formation are driven by the intimate combination of water, inorganic condensation nuclei, dissolved salts, and organics acting as hygroscopic agents; in these cases, microscopic examination of specimens with a cold stage should be planned within the shortest delay. Transmission (for the smallest colloids) and scanning (for larger particles) electron microscopes, in imaging or elemental analysis modes, are used indiscriminately for the characterization of atmospheric entities, though the ESEM, which allows imaging under various conditions of temperature and pressure, is especially useful for water-containing particles larger than 50 nm.

### Aquatic Particles

The study of aquatic particles (i.e., individual entities and their aggregates) encompasses a broad variety of matrices (marine and freshwaters; surface and groundwater; gravitational and capillary water of soils), particle types (nanometer to millimeter; living and nonliving; organics, organomineral mixtures, and minerals), and processes (structure–composition–function relationships; contaminant transport; mechanisms of formation, and dissolution). Sampling of aquatic particles is thus a complex task that will systematically require adaptation of generic protocols to the specificities of the study. Whatsoever, the most relevant investigations are usually obtained by means of correlative electron microscopic approaches, i.e., schemes involving the use of scanning and transmission microscopes to study in parallel whole mounts and resin-embedded specimens (see below), in order to cover the broadest and most accurate physicochemical fingerprint of particles.

Because of the rapid modifications of the physicochemical and microbiological characteristics of natural water samples, initiated by changes in temperature, pH, depth, dissolved O<sub>2</sub> or CO<sub>2</sub>, light, and convection, aquatic samples should be processed for electron microscopy without any delay to avoid dissolutions, precipitations, coagulations, sedimentations, microbial growth, or shifts in chemical

**Figure 1** Overview of the recommended approaches, crucial steps, and possible artifacts relevant to the physicochemical characterization of particulate material in environmental systems by electron microscopies. This scheme does not take into account precautions required for conventional bulk physicochemical analyses.

equilibria affecting colloids and particles, as it also prevails for conventional bulk chemical analyses. Prefractionation of aquatic particles and colloids into narrower classes can be performed by gravitational sedimentation in thermostatted columns, by single or cascade centrifugations/ultracentrifugations, or by single or cascade filtrations/ultrafiltrations. Both fractionation approaches are subjected to artifacts that can be minimized under carefully controlled conditions: Centrifugations must not be performed with highly concentrated suspensions to avoid problems of differential settling; similarly, tangential-flow filtration at low flow rates usually yields no or less polarization concentration than uncontrolled/unstirred cross-flow filtration. Centrifugation and filtration are usually chosen to eliminate the fractions containing the largest particles, although they may be used instead to collect appreciable amounts of particulate material from poorly charged waters (e.g., groundwater, pristine waters), with possible biases caused by apparent coagulation of particles.

Particulate material can also be sampled from natural waters by direct collection onto vertical or horizontal plates (glass, Teflon<sup>TM</sup>, or other plastics) inserted for a while in the water column. Horizontal plates collect sedimenting particles without the drawbacks of conventional sediment traps (shifts in biological activity and redox conditions due to the absence of mixing at the bottom of the trap); vertical plates selectively collect those entities exhibiting a certain affinity for the plate (e.g., adhering bacteria, polysaccharides, Fe-oxyhydroxides).

Particles in soil water require different sampling approaches, depending on the type of water to be sampled. Gravitational water is better collected by means of tension-free lysimeters; these devices integrate, over time, the sampled water, which should thus be recovered shortly after collection to avoid modifications in the size distribution or chemistry of the particles. It must, however, be underlined that tension-free lysimeters may exhibit fairly low collection efficiencies (as low as 10% of the gravitational water, depending on soil texture and porosity). On the other hand, the capillary water of soils can be recovered by means of suction cups, which are made of a porous material (ceramic or plastic), inserted in the soil and connected to a syringe or pump. Due to their porosity ( $\sim 10\text{--}100\ \mu\text{m}$ ), these devices induce a prefractionation of the sampled particulate, and tend to clog with time.

### Soil and Sediment Particles

These types of particles have been the subject of numerous publications related to the identification of

the phases that constitute the soil or the sediment matrix, and to the formation of soils or sediments and their stratigraphic characteristics, but to a lesser extent to the role of particles as carriers and scavengers of contaminants. For these reasons, sampling and specimen preparation protocols for soil or sediment particles are usually less sophisticated than protocols for aquatic particles, provided that one considers soil and sediment particles as static entities having no degree of freedom in their surrounding water.

While the majority of soil samples are characterized by slow reactivities and thus require fewer precautions, hydromorphic soils subjected to rapid hydration/dehydration processes are highly sensitive to redox changes and should be sampled with the greatest care to avoid precipitation of dissolved species ( $\text{Fe}^{2+}$ ,  $\text{Mn}^{2+}$ ) during accidental aeration. Otherwise, soils are usually dried, sieved, and ground prior to being resuspended in various electrolytes for the selective isolation of certain constituents (e.g., organic matter, clays, silts, sands) by sedimentation or centrifugation. These approaches are indeed not recommended for the identification of trace metals, as drastic morphological and compositional modifications are expected at each step of the protocol. Because of their size, soil particulates are most frequently analyzed by SEM, but the ultrastructural analysis of clay micelles or other finely divided components (e.g., iron oxides) requires TEM examination.

The particulate phases building up aquatic sediments represent an intermediate situation between aquatic particles and soil particles: Except for highly consolidated, deep sediments, their water content is large and their reactivity is comparable to, or even larger than the one of hydromorphic soils. Sediments are sampled by means of vertical corers, from which the different season- or event-dependent strata must be subsampled by slicing in a glove box under controlled atmosphere. Textural analysis of sediment particles can be performed by SEM, but more detailed investigations will require dilution of the samples in an electrolyte of composition similar to the interstitial water, prior to specimen preparation for TEM.

### Specimen Preparation

Specimen preparation for SEM requires collection of particulates onto stubs (either directly, or after precollection of entities onto Nuclepore<sup>TM</sup>-type membranes), followed by postcoating, most frequently with a Au or Pt film (for imaging) or C film (for analysis). The maximum achievable resolution

limit that one can expect for SEM of complex heterogeneous environmental particles is  $\sim 10\text{--}50\text{ nm}$ , even for high-intensity FEG-SEM.

Cryotechniques offer an alternative and complementary preparatory technology to chemical fixation and embedding, producing aggregates whose three-dimensional (3D) relationships are spatially 'fixed' by a physical means such as vitrification. The most structurally faithful of the cryotechniques is freeze-etching, which consists of freezing an aquatic sample rapidly enough to vitrify it, mechanically generating a fracture plane through it, and then making a metallic replica of the fracture surface, all the while maintaining the vitrified sample below the recrystallization temperature. The product of the freeze-etch technique is a replica that presents a topographical

image of a colloid or aggregate, untouched by chemical agents and amenable to analysis by TEM.

As compared to SEM, TEM offers a much broader palette of protocols for specimen preparation (see the most prominent procedures in **Figure 2**). Qualitative investigations shall favor the direct deposition of a suspension onto TEM grids (whole mounts), followed by evaporation; this rapid procedure may however induce (1) crystallization of undesirable electrolytes (e.g., salt crystals for marine samples, which can be avoided by rapid rinsing of the grid in ultrapure water), (2) shrinkage of aggregates of flexible organic materials (e.g., exocellular polymeric substances), or (3) coagulation of small colloids.

For the extraction of ultrastructural information (in particular with bacteria, algae, and 3D networks

**Figure 2** Schematic of the most useful qualitative or quantitative specimen preparation schemes for SEM/TEM examination of colloids and particles in aqueous media.

of organic flocs), large size entities (i.e.,  $>1\mu\text{m}$ ) should be visualized by TEM after preparation of thin sections obtained by resin embedding and ultramicrotomy. To avoid artifacts, the choice of an appropriate embedding medium is crucial and should be directed toward a hydrophilic resin (Nanoplast<sup>TM</sup>), rather than more conventional hydrophobic ones (e.g., Spurr<sup>TM</sup>, Epon<sup>TM</sup>, or Araldite<sup>TM</sup>), because the latter require dehydration steps of the sample in organic solvents (acetone, methanol, ethanol, or propylene oxide); these steps are potentially disturbing, as they may cause dissolution of particulate organic moieties and modifications of the morphologies of complex 3D networks containing organic entities. As Nanoplast<sup>TM</sup> produces water molecules during the permeation and polymerization step, it infiltrates readily in porous (e.g., loose and amorphous colloids) and biological (e.g., bacteria) entities, maintaining their fine morphological features.

Ultramicrotomy (see **Figure 2**) of the resin-embedded material should be performed exclusively with a diamond knife to overcome the hardness of mineral particles or biogenic minerals such as silica frustules, which quickly damage conventional glass knives.

Targeted sectioning can also be performed by high-energy focused ion beam (FIB). This emerging technique shall prove highly valuable for environmental science in the near future. In principle, any material (hard inorganic or soft organic entities) is amenable to FIB sectioning.

Ultrastructural investigations require the preparation of ultrathin sections ( $\sim 50\text{--}100\text{ nm}$ ), while larger sections (much easier to obtain, but which should not exceed  $150\text{--}200\text{ nm}$ ) are still amenable to elemental analysis without important biases, even when performing EELS, which theoretically requires the thinnest possible materials.

Probably the most interesting approach to the preparation of specimens for quantitative analysis by TEM is the direct ultracentrifugation of colloidal and particulate entities onto TEM grids. This procedure (see **Figure 2**) yields quantitative whole mounts with evenly distributed particles. For a given suspension, the final coverage of the grid can be finely tuned by varying the volume to be centrifuged, allowing a fairly accurate estimation of the particle concentration in the initial sample, yet avoiding too densely populated grids as is often the case for conventional whole mounts. Entities sensitive to dehydration or redox modifications can be postprotected by horizontally spinning an ultrathin film of hydrophilic Nanoplast<sup>TM</sup> resin. Indeed, the preparation of quantitative mounts can be coupled to sequential fractionation schemes to further narrow the types of particles that are collected onto the grids.

The choice of the grid type and the supporting film is critical for analytical TEM/STEM (in EDS or EELS modes). One must indeed be reminded that the X-rays produced by the analyte under the focused electron beam are emitted in a sphere of volume and will induce secondary X-rays of the materials they hit (e.g., the supporting grid or the pole pieces of the EM column), which may be emitted in the direction of the detector, generating artifact peaks. While Formvar<sup>TM</sup>- or Parlodion<sup>TM</sup>-coated ( $10\text{--}50\text{ nm}$ ; supporting film needed for strength/flexibility), carbon-sputtered ( $3\text{--}10\text{ nm}$ ; needed for thermal/electrical conductivity) copper grids are the best alternative in price and ease of operation for imaging purposes, elemental analysis requires supporting materials that shall not mask the elements of interest: gold grids are preferred for the EDS analysis of trace transition metals; for the identification of carbon-rich entities prepared as whole mounts or quantitative mounts (i.e., without resin embedding), the supporting film must be substituted by a carbon-free  $5\text{--}15\text{ nm}$  SiO film (not adapted for Si-rich entities) or Be film (expensive); large-scale entities (e.g., 3D networks or organic-mineral mixtures) can be collected on holey or Quantifoil<sup>TM</sup> (supporting film with controlled and repetitive holes) or Lacey carbon films for the unconstrained analysis of their unsupported portions, with the risk of a weaker mechanical and electrical stability under the electron beam. Whichever grid is used, the alphanumeric styles shall be preferred in order to keep track of particles of interest over time.

Indeed, staining procedures designed for biological or medical applications can be applied to environmental specimens (in particular in soils, sediments, and natural waters) to either enhance the contrast of poorly electron-opaque organic material (salts of heavy elements, amongst which the most commonly employed are uranyl acetate, lead citrate, phosphotungstate, alcian blue), or selectively stain exocellular polymeric substances (multistep reaction with silver proteinate to yield Ag grains onto polysaccharides). It is regrettable to note that to date it is not possible to clearly identify colloidal humic/fulvic entities, which constitute an important proportion of natural organic materials. On the other hand, highly sophisticated labeling techniques by means of ultraspecific markers (e.g., gold-lectin complexes) should prove, in the near future, to be very valuable to distinguish morphologically similar natural organic macromolecules (e.g., neutral versus acidic polysaccharidic moieties produced by bacteria and algae). In many environmental situations, colloidal organic matter is naturally stained by the major ions present in the electrolyte, and thus requires no staining for simple visualization purposes. It must however be noted

that most existing staining protocols were not designed for environmental specimens (whole mounts or resin embedded) and necessitate careful optimization prior to be used on a routine basis.

## Microscopic Investigation

Electron microscopic investigation of environmental samples has been traditionally performed for years for merely illustrative purposes, although the lateral resolution power and the analytical capabilities of modern electron microscopes are in many situations unique features that can bring unequivocal qualitative and quantitative answers to complex problems in which colloids and particles play a central role. For ease, the qualitative and quantitative approaches of investigation are discussed independently in the following sections, but they should be considered as intimately intermingled within the frame of every cleverly planned correlative electron microscopic investigation, as would be the case for the idealized correlative investigation depicted in Figure 3.

### Qualitative/Semiquantitative Investigation

SEM and ESEM are particularly well suited for the evidencing of surface and textural features of large particulate entities ( $c. >1\mu\text{m}$ ), and for the rough estimate of the particle size distribution. Qualitative 3D morphological information is readily extracted from SEM operated either in secondary electron mode or in backscattered electron mode, and the extent of aggregation between particles (provided that it is not an artifact produced by overloaded specimen stubs) can be documented with a resolution down to  $\sim 50\text{nm}$  without difficulty. Because of its ease of operation, SEM should be selected for the routine survey of samples, in particular for atmospheric and soil particles. Preliminary qualitative surveys should help the operator to focus on either the general trends (e.g., major classes of particle types or sizes or associations) or the significant specificities of the sample (e.g., characteristic aggregation between two types of particles, or prevalence of a narrow size class for a given type of entity).

When combined to conventional bulk experiments and analyses, qualitative use of SEM/ESEM may yield significant progress in the understanding of the studied ecosystem. For example, visualization of the microscopic features of humic and fulvic substances subjected to preliminary changes in pH or ionic strength of the surrounding milieu have greatly contributed to the unequivocal appreciation of the conformational changes of these dominant organics in

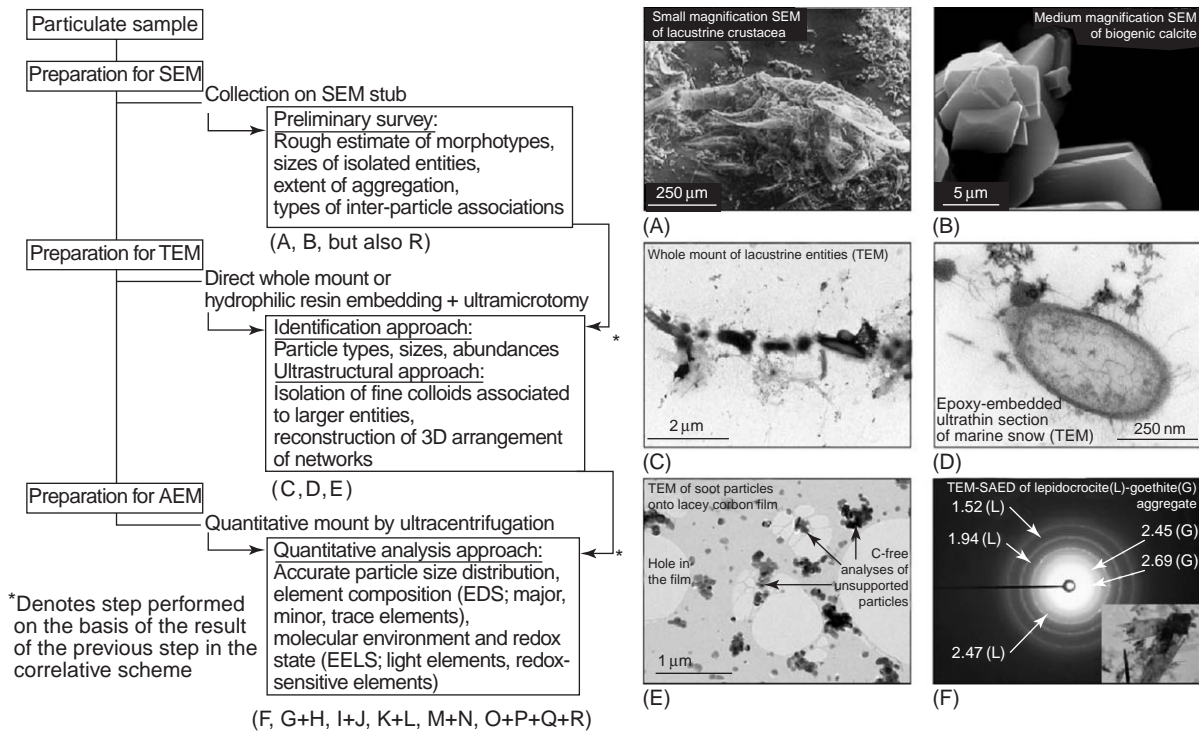

soils, ranging from spherocolloidal entities to flexible and extended fibrils or densely networked 3D systems. Likewise the effect of the intimate associations between clays and fibrillar polysaccharide networks on the stabilization of soil structures has been assessed mainly by means of an SEM. Nonetheless, such investigations require careful specimen preparation techniques (e.g., freeze-drying instead of air drying) aimed at minimizing artifactual conformational changes at every step of the preparation.

Accurate qualitative or semiquantitative investigations on colloidal entities ( $c. <1\mu\text{m}$ ) are better performed by means of a TEM or STEM, with a resolving power down to the nanometer scale, even for complex heterogeneous entities (while a claimed subangstrom resolution is achievable in TEM with aberration corrected electron optics). Whole mounts and quantitative mounts (see Figure 2) are appropriate for semiroutine TEM investigations in the presence of colloidal entities, provided that TEM grids are not too densely populated with large particles and aggregates. In addition, inorganic entities can be checked by qualitative electron diffraction (either in selected area mode or in convergent beam mode) for their potential crystallinity; this is particularly useful for ill-defined particles (e.g., ferrihydrites or partly amorphous oxides) that may reveal locally ordered domains of their atoms, or to distinguish between particles exhibiting the same morphologies and rough composition but different stages of aging.

Ultrastructural TEM characterization of ultrathin resin sections is recommended to reveal, e.g., tiny mineral deposits on bacterial cells, which would be obscured by the thickness-related opacity of bacteria prepared as whole mounts. Likewise, complex large-scale networks of fibrillar exopolymers shall retain their subtle conformation when embedded in the appropriate resin; the reconstruction of their 3D architecture is theoretically achievable by imaging of successive sections, but this requires tedious and extensive image analysis work.

### Quantitative Investigation

Quantitative investigation of natural particulate material necessitates special requirements. In the first place, the specimen must be representative of its original milieu. For example, all particle types initially present in the natural sample must be represented in their right proportions, except if the sample has intentionally undergone controlled fractionation to remove several particle classes. The aggregates present in the specimen must not be artifact expressions of an overloaded TEM grid or of a sample that

would have experienced handling and preparation conditions favoring coagulation of existing entities or precipitation of dissolved species. In that respect, the preparation of quantitative mounts (see **Figure 2**) by direct ultracentrifugation of suspended particles onto TEM grids is certainly the most appropriate approach for quantitative measurements, and most works performed on natural waters, sediments, or soils can be brought to this approach.

Secondly, quantitative investigations need to be performed on a statistically significant number of entities to yield sound measurements. Depending on the expected confidence in the final results, the measurements (size, composition) should be performed on a large set of particles, comprising between 100 and 10 000 entities (see **Figure 3**). When dealing with elemental composition, the measured EDS peak intensities must be calibrated against representative standards; these standards may have to be synthesized in the laboratory under the conditions encountered in the studied ecosystem, because the mechanisms of production of X-rays are influenced by the matrix of the studied material. Standardless analysis is feasible in EDS, but it requires the knowledge of accurate element- and microscope-related parameters. For EELS analysis, relative quantification (i.e., the ratio of one element to another in the particle of interest) is readily obtained by calculation without the need for standards.

Quantitative particle size distributions (either of all types of particles and aggregates present in the specimen, or of a specific type of particle, identified either by morphological criteria or by routine EDS elemental mapping) must be performed on quantitative whole mounts; high-quality micrographs can then be digitized for mathematical morphometry using an image analysis software. The accurate determination of the particle size distribution of atmospheric, aquatic, soil, or sediment entities may yield information on the processes driving their behavior in the milieu (e.g., formation, dissolution, coagulation, sedimentation; see **Figure 3**). It is also possible to estimate the mechanisms of aggregation

of colloids by means of the fractal dimension of aggregates. Provided that micrographs are obtained under carefully controlled conditions of illumination, estimates on the volume of nonspherical particles of known composition can also be obtained by means of image analysis (thickness-dependent opacity of the particles).

Over the past two decades, the clever determination of the composition of nonartifactual environmental particles and colloids by EDS analysis has definitely transformed electron microscopy into a powerful and unique analytical tool. Under optimal conditions, i.e., using an EDS detector equipped with an ultrathin window, even carbon can be quantified, and the detection limits can be as low as  $500\text{--}1000\text{ mg kg}^{-1}$  ( $0.05\text{--}0.1\%$ ), even for submicrometric particles, provided that the trace elements of interest are not overlapped by major or minor elements (see **Figure 3**). The method is particularly well suited for elements emitting  $K\alpha$  peaks in the sensitive  $0\text{--}10\text{ keV}$  energy range, but L-emitting elements can also be measured in this range, provided that they are present as minor or major elements. Quantitative EDS analysis is nowadays the method of choice for the quasiroutine-based detection of trace elements scavenged by particles, or the search for stoichiometric relationships between different elements in similar morphotypes.

Although the ability of EELS techniques (electron spectroscopic imaging, ESI, in imaging mode; EELS in spectrum mode) to detect single atoms with energy resolutions as low as  $0.2\text{ eV}$  in the useful  $0\text{--}1000\text{ eV}$  energy range (in comparison, high-resolution EDS is achieved at  $\sim 150\text{ eV}$ ) has been clearly demonstrated in materials science and even in biological science, EELS is regrettably not commonly used in environmental science. Indeed, the interpretation of spectra is not as clear-cut as in EDS, because (1) the technique is best suited for light elements (although transition metals yield valuable spectral information), (2) the extraction of the EELS K- or L- or even M-edges of elements requires a careful stripping of the substantial background (in the form of a power law

$I = aE^{-b}$ ), (3) the region below  $\sim 100$  eV (plasmons region) is difficult to model with accuracy, (4) there remain uncertainties in the determination of the cross-sections of the M-edges used for absolute quantification purposes, and (5) EELS is theoretically dedicated to specimens with thicknesses below 20–50 nm. It has, however, been demonstrated that the technique can be used to quantify thicker ( $< 500$  nm) environmental particles, although accuracy drops as specimen thickness increases.

In its simplest expression, EELS can be performed in energy-filtered (EF-TEM) or ESI mode, i.e., to acquire elemental maps, but EELS in spectroscopic mode is best suited for quantitative analysis, with a high energy and lateral resolution.

The main advantage of EELS over EDS is its ability to yield molecular information, in the form of specific features at and beyond the edges (see **Figure 3**). The features referred to as energy loss near edge structure (ELNES; extending up to 50–100 eV beyond the edge; counterpart to X-ray absorption near-edge structure, XANES, in X-ray spectroscopy) are fingerprints that bring qualitative information about the molecular environment of the element giving rise to an EELS edge; for instance, the shape of an EELS-ELNES spectrum is different for aromatic, aliphatic, or amorphous organic carbon centers, as well as for inorganic carbon centers. Likewise, EELS spectra acquired with a high-energy resolution (i.e.,  $< 0.5$ – $1$  eV) may reveal the electronic configuration of redox-sensitive elements (e.g.,  $\text{Fe}^{2+}$  versus  $\text{Fe}^{3+}$ , or their mixtures in the same entity;  $\text{Mn}^{2+}$  versus  $\text{Mn}^{3+}$  versus  $\text{Mn}^{4+}$ ). Although exemplary results have already been obtained on pure, crystalline iron minerals and manganese minerals, the approach is far from routine for the complex heterogeneous particles identified in soils, sediments, and natural waters. Similarly, the use of EELS for the redox discrimination of elements of environmental concern such as  $\text{Cr}^{3+}/\text{Cr}^{6+}$ ,  $\text{Cu}^+/\text{Cu}^{2+}$ ,  $\text{As}^{3-}/\text{As}^{3+}/\text{As}^{5+}$ ,

$\text{Sb}^{3-}/\text{Sb}^{3+}/\text{Sb}^{5+}$ , or  $\text{Se}^{2-}/\text{Se}^{4+}/\text{Se}^{6+}$ , has not been reported yet.

### Liquid Crystal Phases

A liquid crystal mesophase is a state of matter intermediate between a solid and a liquid. Strictly, the liquid crystal or mesomorphic state is made up of a

number of orientationally ordered phases that occur between the breakdown of positional ordering of the molecules in a solid and the formation of the amorphous liquid. The breakdown in ordering on passing from a crystal to a liquid can be achieved either by changing the temperature of the material or by dissolving it in a liquid. Liquid crystals formed on heating and/or cooling processes are called thermotropic liquid crystals, and those formed when a material

dissolves in a solvent are called lyotropic liquid crystals. In principle, liquid crystal phases have come to be defined as modifications where the molecules are orientationally ordered but yet are still in dynamic motion. Consequently, this definition also includes soft crystals, where the molecules are rotationally disordered.

Thus, in a classical melting process of a solid to a liquid, the lattice of the solid collapses to give the disorganized liquid where the molecules tumble and rotate freely. At the melt point the molecules undergo large and rapid simultaneous changes in rotational, positional, and orientational order. In melting processes mediated by thermotropic liquid-crystalline behavior, however, there is a stepwise breakdown in order. The incremental steps of this breakdown produce a variety of thermodynamically stable, intermediate states known as mesophases. As liquid crystals have fluid-like structures, the defects that are formed in bulk specimens occur on a large enough scale for the mesophases to be investigated by optical microscopic methods. Similarly, when a lyotropic liquid crystal dissolves in a solvent the crystal state will form the solution via a number of intermediate lyotropic phases. The breakdown in this order can also be charted by polarized light microscopy.

### Thermotropic Liquid Crystals

Like other states of matter, thermotropic mesophases are indefinitely stable at defined temperatures and pressures. Moreover, a thermotropic liquid-crystalline material exhibits reversible phase transitions at well-defined temperatures. For example, the liquid crystal 4-n-pentyl-4'-cyanobiphenyl (5CB) melts from the solid to a nematic liquid crystal at 22.5°C and then from the nematic phase to the liquid at 35.0°C. As a consequence, the characterization and classification of thermotropic phases by microscopy also requires the use of an accurately controlled oven.

The way, or sequence, in which thermotropic transitions occur is defined in the following ways. The liquid crystal to isotropic liquid transition is called the clearing or isotropization point, and this transition, like those between liquid crystal phases, is essentially reversible and occurs with little hysteresis in temperature. The melting point of a material is usually a constant, but the recrystallization process can be subject to supercooling. Mesophases formed on the first heating cycle of a material are thermodynamically stable, and are called enantiotropic phases, whereas phases that are formed below the melt point on cooling cycles, and are revealed

because of the supercooling of the crystal state, are metastable and termed monotropic phases. Both types of phase can be investigated by microscopy.

Thermotropic mesophases are split into two groups as follows. One in which the molecules have rod-like shapes – called calamitic liquid crystals and the other where they have disk-like shapes – called discotic or columnar liquid crystals. Each of these classes can be further subdivided, for example, calamitic mesophases can be split into three groups: disordered or anisotropic plastic crystals, where the molecules have long-range translational order but exhibit rapid dynamic motion; smectic phases, in which the molecules have short-range positional order yet retain layer ordering; and nematic phases, where the molecules are orientationally ordered so that their long axes are on average parallel to one another, this direction is called the director. Again, the molecules exhibit rapid and diffuse molecular motion, principally about their long axes. This motion is related to the Brownian motion observed by microscopy. Examples of the structures of some thermotropic liquid crystals are shown schematically in Figure 1.

**Figure 1** General structures of calamitic and discotic thermotropic liquid crystals. (A) Layered calamitic smectic liquid crystal. The structures of the various types depend on the local packing of the molecules, the extent of the packing, and the orientation of the long axes with respect to the layers. (B) Calamitic nematic liquid crystal. The molecules have no long-range order, and are only orientationally ordered. (C) Ordered columnar discotic liquid crystal. Disk-like molecules form ordered or disordered columns; different column packings give rise to various mesophase structures. (D) Nematic-discotic liquid crystal phase. The disk-like molecules are only orientationally ordered.

### Lytotropic Liquid Crystals

Lytotropic liquid crystals are formed in mixtures of amphiphiles (e.g., surfactants) and solvents, for example, detergents and water. Consequently, these phases are thermodynamically stable at defined temperatures, pressures, and concentrations. Like thermotropics, a variety of structurally distinct modifications exist, which are collectively known as lyotropic liquid crystals.

The quintessential structure of a typical amphiphilic molecule is one where a hydrophilic polar head group is attached to a hydrophobic nonpolar aliphatic moiety. When a lyotropic mesogen dissolves in a solvent the mesophases formed depend on the size of the head group, the number of aliphatic chains present in the amphiphile, and the polarity of the solvent. The phase structures are dependent on the concentration and the degree of curvature produced by the packing arrangements of the amphiphilic molecules, i.e., the ratio of the size of the head group to the aliphatic chain is important. For example, at low curvatures lamellar phases are formed. Increased curvature produces hexagonal phases where the surfactant molecules form columnar structures that pack in hexagonal arrays. Further increase in curvature results in the formation of micellar structures. Typically, when an amphiphile is solvated in a polar solvent, the polar portion of the molecule will interact strongly with the solvent to give a normal micellar structure. Alternatively, in a nonpolar solvent the nonpolar portions of the amphiphile will interact more strongly with the solvent, causing the polar groups to aggregate, thereby producing reversed micellar structures.

### Defects and Textures in Liquid Crystals

Unlike the crystal state, where there are 230 possible space groups, so far only  $\sim 40$  liquid crystal phases have been discovered. Similarly to the way the structure of a crystal can be classified through its birefringent properties seen in the polarized-light microscope, liquid crystal phases (and any accompanying phase sequences) can be classified by thermal polarized-light microscopy. In the case of liquid crystals, however, mesophases are identified from their defect textures, and not from their shapes and/or indexing of crystal faces as is the case for crystals. Moreover, the many defect textures formed by mesophases are dependent on the local ordering of the molecules, and so mesophase structure can be inferred from the analyses of their textures. Thus, it is important to associate microscopic observations with the physical processes and structural changes taking place when a solid melts or dissolves.

As liquid crystals have essentially only weak ordering of the molecules, their textures occur over the whole area of the specimen and the defects that are present appear on a fairly large scale – from about a micrometer or less to hundreds of micrometers in size. This size regime makes the polarizing light microscope an ideal tool for their investigation and classification. The use of a microfurnace, which has viewing ports perpendicular to the direction of the light beam, has made thermal optical microscopy one of the most powerful tools used in the investigation of mesophase morphology for both thermotropic and lyotropic liquid crystals.

The study of defects in liquid crystal systems is rooted in the understanding of defects in the solid state. For instance, crystals are rarely perfect and usually contain a variety of defects, e.g., point defects, line defects, or dislocations, and planar defects such as grain boundaries. In addition to these typical imperfections of the solid state, liquid crystals can also exhibit defects known as disclinations. These defects are not usually found in solids and result from the fact that mesophases have liquid-like structures that can give rise to continuous but sharp changes in the orientations of the molecules, i.e., sharp changes in orientation occur in the director field.

When defects are formed in liquid-crystalline systems the internal energy,  $E$ , rises; however, the entropy,  $S$ , of the system also increases, resulting in a reduction of the free energy. The Gibbs free energy,  $G$ , is related to the internal energy and entropy:

$$G = E - TS \quad [1]$$

and as the number of defects rises the entropy becomes larger, resulting in a decrease in the free energy. Thus, the presence of defects tends to stabilize the system. In practical applications of liquid crystals, e.g., display devices, the presence of defects is very undesirable; consequently, many investigations have been made into their structures and growth, and the information obtained has been used to minimize their presence in applications. Consequently, through alignment techniques it is now possible to create a large area of nematic liquid crystal that is essentially a defect-free monodomain.

### Polymorphism and Paramorphic Textures

A thermotropic liquid crystal is capable of polymorphism, the situation in which a material exhibits more than one liquid-crystalline modification between the solid and liquid phases. For instance, when a calamitic liquid crystal melts it can do so via transitions between a number of smectic phases and the nematic phase. For the purposes of phase

identification by microscopy it is important to consider the nature of the polymorphism and its effects on defect textures. On heating or cooling cycles the imprint of the preceding phase is usually imparted to the phase under observation. Thus, when a crystal melts to a smectic phase, the defect texture produced will bear the imprint of the preceding crystal phase; this is called a paramorphotic texture. In order to obtain the best textures for the purposes of 'reading' them for phase identification, it is important to start by cooling the liquid into the liquid crystal state. The amorphous liquid has no long-range ordering of the molecules, and so the liquid crystal phase formed first will be obtained in its natural texture. Subsequent transitions to other liquid crystal phases will result in them exhibiting paramorphotic textures based on the natural texture of the mesophase formed first. If the reverse process is used, i.e., heating the crystal, then the textures will be based on the defects present in the solid, and as noted above these will be relatively small-scale defects and hard to see and categorize by microscopy. Similar approaches must also be taken with lyotropic, polymeric, discotic, and chiral liquid crystals.

Another useful tool used in conjunction with identification of liquid crystals by microscopy is a listing of the thermodynamic ordering of mesophases. For calamitic smectic phases this ordering is:

where single capital letters  $\text{S}_m$  denote a smectic-like crystal phase where the molecules have long-range order, phases denoted by  $\text{S}_m$  followed by a capital letter are smectic phases where the molecules are arranged in layers and have short-range order, N denotes the nematic phase, which has no layer ordering; and D is a cubic phase. It is possible to use this thermodynamic ordering to eliminate phases in the process of identification. For instance, if a material cools from the liquid to a smectic I phase, then it is safe to say that any phases formed upon subsequent cooling cannot be classed as nematic, smectics A or C, or cubic D because they all occur at higher temperatures than the smectic I phase. Similar thermodynamic sequences are found for discotic and lyotropic liquid crystals, and for variations in the structures of lyotropic phases with respect to concentration.

## Sample Orientation

There are various forms of sample preparation of liquid crystals for optical microscopy, and it is

important that as many are used as possible in phase identification. Moreover, it is essential to recognize that some textures complement one another, thereby giving a complete form of information that is not possible to obtain from isolated textures or specimens. There are essentially two main forms of sample preparation: one where the bulk phase is oriented in one of two ways with respect to the glass microscope slides, and the other where the molecules are aligned over a large area. In the first case textures are obtained that possess a large number of defects, which is useful in phase identification. In the second the number of defects is far fewer as the director of the phase does not vary much in its direction throughout the sample, which is important for physical studies, such as electric field investigations. Both of these options are discussed in the following sections.

## Homeotropic Textures

A homeotropic texture is generally defined as one where the optic axis of the mesophase is perpendicular to the glass substrates, and therefore parallel to the light beam of the microscope. More precisely this refers to an optically uniaxial phase where the optic axis is parallel to the light beam, and therefore under crossed polars the texture appears black or optically extinct. Closely related to this form of sample preparation and bulk orientation are structures for smectic phases where the layers of molecules are parallel to the surfaces of the glass slides but the long axes of molecules may be tilted. In the case of the smectic A phase the molecules are arranged in layers with their long axes perpendicular to the glass; thus, the phase is optically uniaxial and exhibits an optically extinct homeotropic texture (see Figure 2).

A similar arrangement of the molecules can be obtained for the E phase, the only difference being

**Figure 2** Side elevation of a specimen of a smectic A phase that exhibits a homeotropic texture. The molecules, shown as rods, are arranged in more disorganized layers than those shown. (Data from Gray and Goodby, 1984.)

that the molecules have long-range order and are packed in an orthorhombic array. Consequently, the E phase is optically biaxial and as such does not exhibit an optically extinct homeotropic texture, but instead gives a mosaic/platelet texture. Sometimes without concession to rigor, therefore, a texture where the layers of a smectic phase are parallel to the glass substrates is referred to as being 'homeotropically oriented'. Typically, however, the nematic, smectics A and B(hexatic), and crystal B phases for rod-like molecules, and the columnar hexagonal phases for disk-like molecules exhibit homeotropic textures.

### Homogeneous Textures

In the homogeneous texture the molecules are arranged so that their optic axes are at an angle to the path of the light beam. In most cases this is when the optic axes are at right angles to the light beam and parallel to the glass surfaces. This arrangement is also called a planar orientation. Although the director in the planar texture lies parallel to the glass, it can wander in the two-dimensional preparation so that the sample is nonuniform. Thus, in a homogeneous texture of the nematic phase, the molecules are organized in such a way that their long axes are on average parallel to the glass; however, throughout the specimen the long axes need not necessarily point in roughly the same direction.

Both of these textures, planar and homogeneous, can also be obtained in aligned specimens. Alignment essentially refers to the use of a surface coating (see later) that is used to order the molecules preferentially in a certain direction relative to the light beam and the glass surfaces. One major addition to the situation described above is that by manipulating the surface of the aligning agent, e.g., by buffing, the liquid crystal molecules can be oriented over the whole area of the specimen. This is unimportant for homeotropically oriented specimens; however, in relation to homogeneous or planar preparations the degeneracy in the plane of the glass is broken and the molecules tend to point in approximately the same direction.

### Sample Preparation

In its simplest form, the microscopic examination of a liquid crystal involves the use of a polarizing light microscope fitted with long-working-distance objectives and condenser. The long working distance, typically  $\sim 0.5$  cm, is required so that a microfurnace can be placed on the microscope stage. It is also useful to have a selection of waveplates available, e.g., a quarter-waveplate, that can be inserted into the

microscope above the objective but below the upper polarizer, for use in conoscopic studies. Typically, a magnification of  $\sim 100\times$  is required for studies to be made; for example, eyepieces of magnification  $10\times$  and an objective with a magnification between  $10\times$  and  $20\times$  is the most suitable combination. It is important that higher magnifications, e.g.,  $400\times$ , are not used for straightforward observations because the defects can become confusing at this level of magnification, leading to misidentification. However, for conoscopic work magnifications of this order are suitable.

A sample of a thermotropic liquid crystal can be prepared by placing a small amount of the material between a clean glass slide and a coverslip, and inserting it into the oven of the microscope. For a lyotropic liquid crystal either the compound can be dissolved in a solvent directly on the microscope stage at room temperature whilst under microscopic observation, or else a solution of known concentration can be made up and sealed in a glass cell, which can then be inserted into the oven. In each of these cases defect textures will be observed. Transition temperatures can be determined by heating or cooling the sample. Typically heating/cooling rates of  $0.1^\circ\text{C min}^{-1}$  are used to determine these values. The reversibility and sharpness of the liquid crystal phase transitions are extremely sensitive to the quality or purity of the material. A pure liquid crystal should show reversible transitions, within a degree, for the heating and cooling cycles.

### Homeotropic Alignment

Homeotropic alignment can be achieved in a variety of ways, for example, by using very clean glass, by using a surface aligning agent, or by using free-standing film techniques. Surface treatments include using materials that have a strongly polar surface interaction but that can be removed from the glass by washing, e.g., lecithin, or aligning materials that can be chemically bound to the glass, e.g., octyldimethylchlorosilane. The surface of the slide is usually treated with a very dilute solution ( $\sim 1\%$ ) of the aligning material in a solvent that will completely wet the glass. The slide is then dipped into the solution and the excess solution and solvent are removed to leave a monolayer of the aligning agent on the glass. Cooling the liquid crystal from the liquid on such a surface will cause the molecules to become aligned with the long aliphatic chains of the surfactant, thereby causing the liquid crystal to stand up on the glass to yield a homeotropic texture.

A homeotropic texture can also be obtained for smectic phases by creating a freely suspended film of

the liquid crystal where the planes of the layers in the phase are parallel to a supporting glass or metal plate. This preparation can be obtained by drawing a liquid crystal, in either its smectic A or smectic C phase, across a small hole (1–2 mm) drilled in a glass or metal plate while the sample is in the oven. This technique creates specimens of extremely good quality with well-defined numbers of layers that can also be used as samples for X-ray analysis.

### Homogeneous Alignment

Homogeneous alignment can be achieved in a variety of ways, for example, from simply using glass slides that have been touched by human hand to using surfaces on which SiO may have been obliquely evaporated. For microscopic observations slightly unclean glass usually works well, as do surface preparations using aligning agents such as poly(vinyl alcohol) (PVA) or nylon. Surface aligning agents have the advantage that they can be unidirectionally buffed to give unidirectionally aligned specimens that can be used in a variety of physical studies. However, for the purposes of phase identification, samples that show a variety of defects are of more practical use.

Nylon or PVA can be coated on to the surface of slides by dissolving a small amount of the polymer (~1%) in a suitable solvent and then dipping the glass slide into the solution or by spin coating the solution directly on to the glass. The excess solution is drained off and the remaining solvent evaporated. Upon drying, the slide can either be used 'as is' to give an unaligned sample, or it can be unidirectionally buffed to produce an aligned specimen. When a liquid crystal is cooled from its isotropic liquid phase on such a surface it will form a preparation in which the long axes of the molecules lie in the plane parallel to the support.

### Shearing Techniques

One good way in which to probe a liquid crystal specimen is to subject it to mechanical shearing while in the microscope oven. This can be done by inserting a metal instrument into the microscope oven and dislodging the upper glass plate of the sample. Furthermore, pressurizing the specimen from above, thereby decreasing its thickness, results in the sample becoming more homeotropic in nature; shearing from the side can result in the conversion of a homeotropic texture to a homogeneous form. In the special case of the cholesteric phase, shearing the homogeneous texture exclusively results in the formation of a Grandjean plane texture, i.e., the helical axes of the structure of the mesophase are converted from parallel or at various angles to the glass to being perpendicular.

## Applications in the Identification of Liquid Crystal Phases

In the following sections some of the more common liquid crystal textures utilized in the classification of thermotropic calamitic mesophases are described. It should be noted that similar examinations of defects are used to classify discotic, polymeric, and lyotropic phases.

### Schlieren Textures

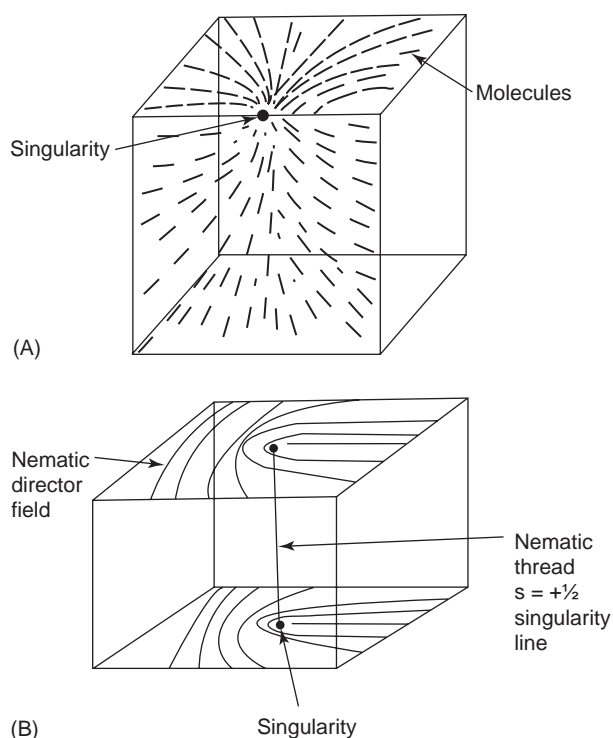

'Schlieren' textures are very common in liquid crystals and are usually easily identified and classified. These patterns are observed in homogeneously oriented nematic phases and for smectic phases where the long axes of the molecules are tilted with respect to the layer planes and the layers are arranged parallel to the surface of the glass. Thus, 'schlieren' textures occur for the nematic phases of both calamitic and discotic materials, and for the tilted smectic phases C, I, and F.

Between crossed polars these defects appear as dark lines or brushes with curved or irregular shapes that correspond to extinction positions of the director and molecular long axes. Thus, the director can be either parallel or perpendicular to the polarizer and analyzer. The brushes tend to cover the specimen in rather a continuous way, indicating the liquid-like nature of the mesophase. The points where the brushes meet are called singularities in the texture (see Figure 3A). For nematic phases two forms of schlieren defect are found, one where two brushes meet at a point and one where four brushes meet. All tilted smectic phases (C, I, F, and ferroelectric C), except for the antiferroelectric phase, exhibit four brush singularities. Therefore, this provides a simple way of distinguishing between smectic and nematic phases. It should be noted that phases such as smectics A and B(hexatic) and crystal phases B(crystal), E, G, H, J, and K do not exhibit schlieren textures and so this narrows down the possibilities for phase identification.

The number of brushes that emanate from point singularities (where  $s$  denotes the strength of the singularity) in schlieren textures are classified as:

$$s = \pm \frac{\text{number of brushes}}{4} \quad [2]$$

where the number of brushes corresponds to the number of dark lines emanating from a point defect in the texture. The sign of the defect ( $\pm$ ) is given by the direction of rotation of the brushes when the polarizer and analyzer are rotated together, i.e., rotation of the brush in the same direction as the rotation of the polarizer and analyzer is defined as

**Figure 3** Singularities in the schlieren textures of nematic phases: (A) a point singularity (the rod-like molecules are shown as short lines), and (B) a nematic thread or  $\pi$  disclination joining two singularities on the surfaces of the glass (the orientation of the director field is shown by the black curved lines).

being positive. Thus, defects with  $s = +1/2$ ,  $-1/2$ ,  $+1$ , and  $-1$  are possible, but if the  $s$  values are added up over the whole sample the resultant value will be approximately zero. Furthermore, neighboring singularities that are connected by brushes tend to have opposite signs and therefore will attract one another. They will annihilate if their respective  $s$  values add up to zero.

Thus, a singularity is a point where the director field abruptly changes, i.e., a disclination occurs in the texture. **Figure 4** shows a variety of different ways in which the director can change about points to give schlieren patterns, examples of which are shown in **Figure 5A**. For nematic phases the lines shown represent the average direction of the long axes of the molecules; however, for smectic phases the lines are associated with the direction of the tilts of the molecules.

It is also possible to have points with  $s = \pm 1/2$  joined by line singularities in the nematic phase: these  $\pi$  disclinations, which are commonly known as threads, pass through the preparation almost perpendicularly with the ends attached to the glass surfaces. **Figure 3B** shows the topology about  $s = +1/2$  singularity line; the end appears as a point on the

**Figure 4** Schlieren textures in calamitic thermotropic liquid crystals: (A) two brushed singularities seen exclusively in the nematic phase, and (B) four brushed singularities seen for both smectic and nematic phases. The dark lines show the orientation of the director. (Data from Gray and Goodby, 1984.)

glass as  $s = +1/2$ . In the figure the director field is drawn on the upper and lower glass surfaces. Similarly, for two points joined together that have  $s = \pm 1$  topologies, the resulting line singularity will be a  $2\pi$  disclination. The parameter  $s$  can also be considered as related to the strength of the disclination, and  $s \times 2\pi$  gives the angle by which the director rotates about a closed circuit around the center of the defect.

### Focal-Conic Textures

Focal-conic textures are patterns that are usually observed for smectic phases where the layers are allowed to form curved structures. Such mesophases must therefore have only short-range periodic order, as long-range ordering serves to destabilize curved structures. Typically, focal-conic domains

(A)

(B)

**Figure 5** Photomicrographs of liquid crystal textures seen in the polarizing microscope. (A) The Schlieren texture of a smectic I phase. (B) The focal conic texture of a chiral smectic C\* phase, which has a helical structure, forming at a transition from the liquid. The pitch of the helix shows up as parallel lines that are parallel to the molecule layers (each line corresponds to about a thousand molecular layers). The pitch lines reflect accurately the layer structure in the focal-conic domain. ((A) Courtesy of JW Goodby, University of Hull, UK, with permission. (B) Reproduced with permission from Gordon and Breach, Switzerland.)

are observed in homogeneously oriented samples where the director is nonuniform in the plane of the preparation. This texture is also the natural texture of the smectic A and smectic C phases; consequently, smectic phases formed on cooling either of these modifications will exhibit paramorphic textures based on, but not necessarily true, focal-conic defects.

Curvature of the layers in the smectic state is compatible with the formation of cylindrical, tore and Dupin cyclide defects. The most common defect is the Dupin cyclide and therefore is discussed in more detail. When the smectic A phase nucleates from either the liquid or the nematic phase, it can do so with the formation of curved structures called *bâtonnets* (see **Figure 6**), i.e., layers of molecules add to a

**Figure 6** Photomicrograph of *bâtonnets* forming on cooling from the isotropic liquid into a smectic A phase, seen in the polarizing microscope (100 $\times$ ).

nucleation site almost in the fashion of an onion skin. For a cylindrical structure the growing phase will resemble a jellyroll. However, when the nucleating jellyroll loops back on itself to form a ring, a situation will be produced where the cylindrical layers will form a set of concentric tubes like a number of innertubes one growing on the outside of another, i.e., tores. When the circular tubes grow at a disproportionate rate on one side relative to the other, a lop-sided circular tube, or a Dupin cyclide, is formed. **Figure 7** shows the structure of a focal-conic domain; the side elevation shows the concentric tubes with one side growing at a faster rate than the other. As layers are added they will eventually meet and fill in the hole at the center of the ring. As more layers are added they will cover the outer surface but a dimple will still remain at the point where the layers of the two sides meet. The locus of the dimple is described by a hyperbola. An ellipse is similarly found to describe the growth of the layers in the plan or horizontal section of the defect as shown. Thus, the hyperbola forms the locus of the apices of cones of revolution of which the ellipse is a common section.

**Figure 8** shows a section through a focal-conic domain. On the surface of the domain the long axes of the molecules are radially oriented with respect to the apex of the conical domain, but inside the layers curve so that there is a mismatch of the long axes along the hyperbola. Along the edge of the ellipse the molecules are also radially distributed; therefore, the hyperbola and ellipse show up as lines of optical discontinuity in the polarizing microscope, i.e., they appear as black crosses. **Figure 9** shows a typical texture of focal-conic defects in the smectic A phase. **Figure 5B** shows how the layers are highlighted by in a helical smectic C mesophase.

**Figure 7** Structure of a focal-conic domain of a smectic A phase. The growth of a Dupin cyclide (both plan and side elevation) where the layers are depicted as circles and the molecules are only shown in one layer: (A) a plan view, and (B) a section through the fully developed domain. (Data from Gray and Goodby, 1984.)

When a smectic A phase is cooled from the nematic phase or the isotropic liquid and further smectic phases are formed, then the textures produced are paramorphotic of the preceding A phase. For instance, on cooling at a smectic A to smectic C transition, the molecules in the focal-conic domain will tilt and the structure of the domain will become distorted and patchy. This effect is called breaking of the focal-conic domains and is characteristic of changes that occur in the texture when the molecules tilt, i.e., broken focal-conics are formed for the smectic C phase. Alternatively transitory, rather than permanent, changes can occur in the focal-conic texture for certain phase changes. For example, at the smectic A to smectic B transition transitory bands, called transition bars, can appear across the focal-conic domains parallel to the planes of the ellipses. These are due to changes in the positional correlation length of the molecules at the transition. Bands can

**Figure 8** A three-dimensional representation of a focal-conic domain. Part of the domain is cut away to reveal the inner structure. (Data from Gray and Goodby, 1984.)

**Figure 9** Photomicrograph of the focal-conic texture of the smectic A phase seen in the polarizing microscope ( $100\times$ ). The black crosses are optical discontinuities formed by ellipses and hyperbolae.

also be formed at the transition to the E phase, but in this case they are permanent and remain throughout the temperature range of the phase.

By studying paramorphotic patterns and the way that they appear in focal-conics, phase identification can be accomplished and information on mesophase structure can be obtained. However, the problems of phase identification are greatly eased when the focal-conic texture is accompanied by a homeotropically oriented texture. For example, the smectic A phase can exhibit the unbroken focal-conic and optically extinct homeotropic textures together, whereas the smectic C phase exhibits broken focal-conic and schlieren textures, and the E phase exhibits banded focal-conic and mosaic textures. Thus, the

**Figure 10** Photomicrograph of the mosaic texture of a crystal J phase formed in a free-standing film seen in the polarizing microscope (100 $\times$ ).

generation and examination of a combination of various textures together in one preparation is a powerful technique for classifying mesophases.

### Mosaic Textures

As noted in the introduction, liquid crystals have differing degrees of order, and for the more ordered crystal-like phases bending of their structures is energetically unfavorable. As a consequence these phases prefer not to form schlieren or focal-conic textures, and instead form mosaic textures, where each domain is separated from neighboring domains by grain boundaries. However, the molecules in each domain have the same relative orientation. The domains in liquid crystal phases can have fairly large sizes (hundreds of micrometers) and irregular shapes; in some cases, where the molecules have extensive long-range order, 'twinning' can be observed.

Mosaics can be observed for a number of phases, for example, smectics F and hexatic B, and crystals B, E, G, J, K, and H, all exhibit mosaics of one form or another (see Figure 10). It is very difficult to identify these phases from their mosaic textures as they all look very similar. Two exceptions are worthy of note: the E phase, because it is biaxial, has a very characteristic mosaic pattern where the domains tend to overlap to give a ghost-like appearance; and the B phases, where the mosaic texture is often accompanied by a homeotropic texture that remains optically extinct on rotation of the microscope stage. Figure 11 shows a variety of mosaic textures where the molecules are either tilted or perpendicular with respect to the layer planes.

### Specific Problems

There are very few problems in using optical microscopy with respect to the preparation of the samples;

**Figure 11** The mosaic textures of smectic phases showing the side elevations of the domains: (A) the orthogonal smectic phases and (B) the mosaic texture of a smectic phase where the long axes of the molecules are tilted with respect to the layer planes. (Data from Gray and Goodby, 1984.)

the only major concerns might be with either decomposition of a material under examination or the quality of its alignment. The first can be minimized by heating the specimen in an inert atmosphere, e.g., nitrogen, and the second can usually be resolved by altering the aligning agent.

### Thermal Optical Microscopy of Liquid Crystals

Thermal polarized light microscopy of liquid crystal systems still primarily involves the identification of phase types. Recently, however, a number of novel phases with complex structures have been discovered and detailed examinations of the configurations of their defects are required in order to provide a basis for future phase classification. Thermal microscopy is also used extensively in examination of the alignment processes of liquid crystals, and, in a related context, electric-field studies on meso-phases are carried out in aligned cells. Electric-field studies are now used as adjuncts to phase classification, e.g., antiferroelectric phases are sometimes identified in the microscope with the aid of electric-field studies.

Thermal optical microscopy also finds extensive use in the analysis of optically active mesophases where the molecules can form macroscopic helical structures. For instance, the pitch length for helical phases can be determined by measuring the distances between the defect lines formed through the interaction of the helical structure and the surface of the preparation. The microscope can also be used as polarimeter to determine helical twist direction for homeotropically aligned helical mesophases.

Thus, since 1921 the polarizing microscope has proved to be a cheap yet powerful tool in the investigation of liquid crystals, and no investigation of a mesogenic material is considered complete without a preliminary examination in the microscope.

## Introduction

The transmission electron microscope (TEM) has evolved into a sophisticated instrument capable of providing structural and chemical information from solid materials over a wide range of magnification, to a level of spatial resolution that is unapproachable by most other techniques. The TEM offers a wide variety of imaging, diffraction, and microanalytical modes that can be used individually or in combination to extract essential information about semiconductor materials and devices. Techniques that are widely available and commonly used include transmission and high-resolution electron microscopy, electron-energy-loss and energy-dispersive X-ray spectroscopy, and convergent-beam electron diffraction. Advanced methods include electron

holography, cathodoluminescence (CL) and Z-contrast annular-dark-field (ADF) imaging. The purpose of this article is to review briefly, with selected representative examples, applications of these various imaging, diffraction, and microanalytical modes of the TEM to semiconductor materials. These specific applications have been chosen to demonstrate the versatility and power of the TEM for solving relevant technological problems.

## Background

The TEM utilizes a finely focused electron beam and several intermediate stages of magnification to obtain a highly enlarged image of the specimen region of interest. Electron wavelengths are typically much less than 0.1 nm, but unavoidable lens aberrations restrict optimum image resolutions to the range of 0.25–0.16 nm for operating voltages of 200–400 kV. At this resolution level, details of atomic configurations for many types of inorganic materials are still obtainable in low-index crystallographic projections.

Thermal optical microscopy also finds extensive use in the analysis of optically active mesophases where the molecules can form macroscopic helical structures. For instance, the pitch length for helical phases can be determined by measuring the distances between the defect lines formed through the interaction of the helical structure and the surface of the preparation. The microscope can also be used as polarimeter to determine helical twist direction for homeotropically aligned helical mesophases.

Thus, since 1921 the polarizing microscope has proved to be a cheap yet powerful tool in the investigation of liquid crystals, and no investigation of a mesogenic material is considered complete without a preliminary examination in the microscope.

## Introduction

The transmission electron microscope (TEM) has evolved into a sophisticated instrument capable of providing structural and chemical information from solid materials over a wide range of magnification, to a level of spatial resolution that is unapproachable by most other techniques. The TEM offers a wide variety of imaging, diffraction, and microanalytical modes that can be used individually or in combination to extract essential information about semiconductor materials and devices. Techniques that are widely available and commonly used include transmission and high-resolution electron microscopy, electron-energy-loss and energy-dispersive X-ray spectroscopy, and convergent-beam electron diffraction. Advanced methods include electron

holography, cathodoluminescence (CL) and Z-contrast annular-dark-field (ADF) imaging. The purpose of this article is to review briefly, with selected representative examples, applications of these various imaging, diffraction, and microanalytical modes of the TEM to semiconductor materials. These specific applications have been chosen to demonstrate the versatility and power of the TEM for solving relevant technological problems.

## Background

The TEM utilizes a finely focused electron beam and several intermediate stages of magnification to obtain a highly enlarged image of the specimen region of interest. Electron wavelengths are typically much less than 0.1 nm, but unavoidable lens aberrations restrict optimum image resolutions to the range of 0.25–0.16 nm for operating voltages of 200–400 kV. At this resolution level, details of atomic configurations for many types of inorganic materials are still obtainable in low-index crystallographic projections.

The conventional transmission electron microscope (CTEM) uses a broad, usually circular, beam of electrons, with a diameter of  $\sim 0.5\text{--}1.0\text{ }\mu\text{m}$  across, which is transmitted through a suitably thinned specimen. The final magnified image is visible on a fluorescent screen at the base of the microscope or it can be displayed on a television monitor via a suitable image pickup system. The image can then be recorded on photographic film or a digital camera, or else stored on videotape for later review of dynamic events. The scanning transmission electron microscope (STEM) involves the rastering of a focused nanoprobe across the sample in synchronization with the detection of electrons transmitted through the sample, which are then used to form an image by intensity modulation of a display monitor. When the nanoprobe is stopped at specific sample locations, elemental information about the irradiated area can be obtained through detection of the characteristic X-rays emitted by the sample or by examination of the energy spectrum of the transmitted electrons. The complementary information provided by these latter microanalytical signals can be highly useful in elucidating the origins of local defects or inhomogeneities in semiconductor materials.

## Sample Types and Preparation Methods

In the field of semiconductors, there are many different types of specimen that are of interest. Depending on the particular application or problem area, the electron microscopist might focus on such features as dopant clusters, point, line or planar defects, or buried interfaces, etc. A serious restriction of TEM methods is that only relatively thin sections of material can be examined. Since the regions of interest often involve microstructural features that must be evaluated in at least two, and sometimes three dimensions, it often becomes necessary to prepare specimens for observation in two orthogonal directions, i.e., plan-view and cross-section. Plan-view specimens are usually straightforward to prepare, sometimes only involving chemical etching or mechanical polishing. Conversely, the preparation of cross-sections may involve the use of costly equipment such as focused-ion-beam systems, and it can often be quite time consuming.

### Plan-View Specimens

The simplest cases involve passive, and usually selective, wet-chemical etching of material such as the substrate, so that overlayers which may be 100 nm or less in thickness are left for examination.

Typical examples include the selective removal of III–V buffer layers leading to float-off of thin, epitaxially grown III–V overlayers, removal of silicon substrates from diamond films grown by chemical vapor deposition (CVD), and the removal of metal contacts from the underlying semiconductor. In similar fashion, buried layers can often be extracted using a sequence of suitable etchants, and when this layer is not contiguous, a thin amorphous carbon film can be deposited to give structural integrity to the layer. When bulk material needs to be examined, thinned regions must be produced by other methods. Thinning can be accomplished, for example, by mechanical polishing and dimple-grinding followed either by chemical jet-etching or ion-beam milling. The latter approach is somewhat slower but will generally lead to larger areas of thinned material.

### Cross-Sectional Specimens

The cross-sectional geometry is required when the features of interest are buried within the material or else distributed throughout its depth. For example, it may be necessary to assess the planarity of buried interfaces, or to establish the distribution of any interfacial defects, their width and composition, and the presence of secondary phases. Cross-sectional specimens are usually prepared by gluing the material of interest face-to-face with additional supporting material. Mechanical polishing and then dimple-polishing of a thin slice cut from this stack reduce the total overall thickness to  $\sim 5\text{--}10\text{ }\mu\text{m}$ . Finally, argon-ion-beam milling is used to achieve perforation through the cross-sectional film. Thin areas of the interface are then created where the perforated hole intersects the glued faces. Damage to many semiconducting materials during cross-sectioning can be reduced by ion-milling with the specimen held at liquid nitrogen temperature. Some materials, such as indium- or zinc-containing compounds, benefit from additional milling with reactive ions such as  $\text{I}^+$ . Specimens containing materials with very different ion-milling rates, such as those grown on sapphire substrates, have a tendency to form ‘bridges’ of material spanning the perforation. These bridges can often be overcome by ion-milling at very low angles of incidence along the surface ( $\sim 1^\circ\text{--}2^\circ$ ) or by using the technique of chemically assisted ion-beam milling.

In many cross-sectional specimens, especially epitaxial systems, the choice of crystallographic direction that will be aligned parallel to the electron beam direction during TEM observation can be very important. For example, in binary, ternary, and quaternary alloys of cubic (zinc blende) III–V materials, the boundaries between layers are much more clearly

revealed if the sample is observed with the [100] projection parallel to the electron beam direction, rather than [110], because diffracted beams have greater chemical sensitivity in this projection. Specimens having this preferred [100] orientation can often be prepared relatively quickly without ion-milling by using a cleaved-wedge method. This preparation involves applying controlled pressure to small squares of material  $\sim 200\mu\text{m}$  thick, which cleave along the [110] direction to produce  $90^\circ$  wedges about the [100] direction. The thinnest edges of these samples can then be viewed by TEM when the sample is suitably mounted. Wedges with shallower angles, and therefore larger regions of thin area, can sometimes be produced by cleavage along higher-index planes.

Cross-sectional specimen observation is usually the preferred geometry for studying TEM specimens of actual semiconductor devices. When the devices are relatively large, or when similar structural units are repeated many times, the preparation methods described above can be employed with high success rates. However, when a specific part of a device must be targeted, for example in integrated-circuit failure analysis, then newer techniques based either on carefully controlled mechanical polishing at very shallow wedge angles, or with a focused-ion-beam system, are becoming the preferred method of preparation.

## Imaging and Diffraction

### Transmission Electron Microscopy

The standard operating mode for the TEM is termed amplitude or diffraction contrast imaging. Electrons that have passed through the sample are focused to form the highly magnified image of the region of interest on the final viewing screen. The image contrast results from the use of a suitably small objective aperture that blocks most of the scattered (or diffracted) electrons, which thus do not reach the final image plane. Crystalline samples can be aligned by reference to the electron diffraction pattern (EDP), to ensure that the specimen orientation relative to the incident beam direction will satisfy a strongly diffracting condition. Under such conditions, common types of defects are easily recognized by their characteristic appearance and second-phase materials are often conspicuous. Moreover, characteristic crystal lattice spacings and angles can also often be measured and identified from the EDP.

The availability of a crystalline substrate or supporting medium often provides a useful method for orientation of the sample during observation within the electron microscope. By using the substrate EDP

**Figure 1** Diffraction contrast image showing a cross-sectional view of a Si-based integrated memory device prepared for electron microscopy observation by focused-ion-beam milling.

as a reference, it becomes possible to align the substrate surface normal, or the internal interface of interest, in such a way that they are aligned perpendicular to the electron beam direction. The microstructure of thin films or multilayers can then be characterized as a function of lateral position as well as distance from the substrate (or previous layer). Nevertheless, it must be appreciated that imaging of complex devices represents a serious challenge to the electron microscopist because of the inherent difficulty of preparing electron-transparent regions across the entire structure simultaneously. **Figure 1** is an example of a diffraction contrast image where this thinning has been successfully accomplished: it shows a cross-sectional view of a silicon-based integrated memory device that has been prepared for microscopy using a focused-ion-beam milling system.

### High-Resolution Electron Microscopy

When a large objective aperture (or perhaps none at all) is used, one or more diffracted beams can interfere with the transmitted beam in forming the high-resolution image. The image contrast then depends on the relative phases of these various beams, so this operating mode is usually termed phase-contrast imaging. Under optimum imaging conditions, these phase-contrast images can be interpreted directly in terms of the projected crystal potential, with a spatial resolution that is often better than  $0.2\text{ nm}$ . Individual atomic columns can thus be resolved in many crystalline inorganic materials, at least when they are viewed in low-index zone axes projections where the atomic separations are comparatively large in projection. For highest resolution, the specimen thickness should ideally be less than  $\sim 10\text{ nm}$ . High electron doses (typically  $\sim 500\text{--}2000\text{ electrons }\text{\AA}^{-2}$ ) are also required. Thus, specimens must be relatively

resistant to electron irradiation effects, and organic materials cannot be imaged directly under such conditions. Furthermore, dynamic events can be followed in real time without significant loss of resolution by using a specimen heating holder, and adding a TV image pickup system to the base of the microscope lens column.

High-resolution electron microscopy has been applied to the characterization of a diverse range of inorganic materials. Important applications include determining the detailed microstructure of defects, interfaces and grain boundaries, investigating nanocrystalline features in amorphous films, and studying small particles in heterogeneous catalysts. From a technological point of view, the characterization of semiconductor interfaces continues to be a very important application. Interfacial structure is critical to the viability and operation of many devices. Examples of such interfaces include superlattices and multiple quantum well (MQW) structures consisting of alternate layers of different III-V semiconductors and having optoelectronic applications; heteroepitaxial layers of II-VI semiconductors grown on III-V substrates; heteroepitaxial systems such as GaAs grown on silicon with potential applications to integrated optoelectronics; and metal/semiconductor contacts for discrete devices. High-resolution images are able to provide details about the interfacial structure that is usually unavailable from any other technique. As an example, **Figure 2** shows a GaAs/GaN/GaAs heterostructure as grown by molecular-beam epitaxy (MBE). There is a large lattice mismatch between the two materials and a high density of lattice

defects in the intermediary GaN layer. Nevertheless, it is clear that high-quality epitaxial growth of the uppermost GaAs layer has been achieved.

### Convergent-Beam Electron Diffraction

The technique of convergent-beam electron diffraction (CBED) utilizes a convergent focused beam to obtain diffraction patterns from small specimen regions. CBED patterns are comprised of disks of intensity (rather than spots) and these disks are rich in detail that can often be exploited to reveal important aspects about the specimen. Applications of CBED range from the measurement of specimen thickness, to the determination of crystal symmetry (i.e., point and space groups) for analysis of new crystallographic phases and analysis of phase transitions, and determination of amplitudes and phases of low-order structure factors. The technique can also provide very accurate measurements of small changes in lattice parameters resulting from local changes in composition or lattice strain. When the specimen is sufficiently thin ( $< 50$  nm), then the spatial resolution is determined primarily by the size of the focused incident probe. When very small probes are used ( $< 1$  nm or less in diameter), the technique is termed nanodiffraction. A field-emission source of electrons is then essential since the beam intensity at the specimen level would otherwise be too low to be usable. Nanodiffraction is particularly useful for studying very small particles, and for determining local order and crystal symmetry in thin films of near-amorphous materials or disordered crystals.

The high sensitivity of CBED patterns to small changes in lattice parameter is illustrated in **Figure 3**. These two CBED patterns compare the central bright-field CBED disk for a thin GaN film oriented close to  $[10\bar{1}0]$ , with the corresponding disk from a thin epitaxial  $\text{Ga}_{0.96}\text{In}_{0.04}\text{N}$  quantum well layer. The fractional difference in lattice parameter due to the difference in composition is considerably less than 0.5%, but the relative positions of the dark

**Figure 2** High-resolution electron micrograph showing GaAs/GaN/GaAs heterostructure grown by molecular beam epitaxy.

**Figure 3** Comparison of central disks from CBED patterns: (A) GaN and (B)  $\text{Ga}_{0.96}\text{In}_{0.04}\text{N}$ . Note relative shifted positions of dark higher-order Laue zone lines due to differences in lattice parameter.

higher-order Laue zone (HOLZ) lines, which are the dark diagonal lines crossing the disk, are readily apparent. The shift in these HOLZ lines as a function of the probe position along the quantum well was used to determine variations in the local In concentration with high precision and spatial resolution.

## Spectroscopy

### Electron-Energy-Loss Spectroscopy

Electron-energy-loss spectroscopy (EELS) uses the characteristic energy-loss spectrum of electrons that have been transmitted through the sample. Since the amount of electron-energy loss is related directly to the ionization energy, which has a well-known characteristic behavior for any given element, information can be obtained about elemental composition, chemical bonding, and electronic structure. The typical EELS spectrum contains a monotonically decreasing background and several broad superimposed peaks, each of which has an energy that is directly related to a particular inelastic scattering process. The spatial resolution is determined primarily by the diameter of the incident focused probe provided that the sample thickness is not excessive. The EELS technique can be used to observe band structure effects, to provide chemical information such as distinguishing between allotropes, and to determine oxidation states, as well as to measure short-range order (i.e., determination of radial distribution function). Quantitative elemental analysis, both fixed-point and time- and position-resolved, is possible with sensitivity levels sometimes approaching or exceeding better than one atomic percent. Specimens that are intended for microanalysis must be thin (<50–100 nm) to avoid multiple scattering effects that can cause loss of spectral resolution and sensitivity. Their surfaces must also be carefully cleaned if quantitative analysis is required since substantial carbon contamination is otherwise liable to occur during small-probe observation. It is becoming common-place to clean samples, and the sample holder, in a plasma-cleaning device immediately prior to insertion into the electron microscope. Finally, it needs to be appreciated that irradiation effects may occur during examination with the intense stationary probe, which can significantly alter the local microstructure and composition.

For applications in the semiconductor field, EELS is commonly used when elemental information is needed about depletion regions or segregation profiles, for example following ion implantation, amorphization, and recrystallization, or as a result of defect cluster precipitation during annealing cycles.

**Figure 4** Electron-energy-loss spectra, with background stripped, showing Si-L fine-edge structure originating from different Si-containing compounds.

Diffusion profiles across interfaces can also be extracted from EELS data provided that the effects of the probe size and shape are properly taken into account. An interesting comparison of the near-edge fine structure in EELS spectra from four Si-containing materials is shown in **Figure 4**. The differences in the shapes of these spectra, which can be replicated theoretically, are due to differences in composition as well as changes in the local chemical bonding (i.e., the local atomic environment).

### Energy-Dispersive X-Ray Spectroscopy

Energy-dispersive X-ray (EDX) spectroscopy utilizes the characteristic spectrum of X-rays that is emitted by a sample, following initial excitation by the high-energy electron beam. Information about the elemental composition of the sample can be obtained, where the spatial resolution is determined by the probe size, any beam broadening occurring within the specimen, and the effects of any backscattered electrons on the specimen around the point of analysis. EDX is relatively simple and can be used to provide rapid qualitative microanalysis. Quantitative elemental analysis can also be achieved, with an

accuracy approaching a few atomic percent. The technique can be used for atomic site and species determination using electron channeling. Note, however, that quantitative EDX analysis implies thin specimens, and (pre)calibration of the EDX analysis system using standards of known composition is required. EDX is generally better suited than EELS for detecting elements of high atomic number ( $Z$ ) but the technique does not usually provide local bonding information, unlike EELS. Low- $Z$  elements ( $Z < 11$ ) are not detectable by some EDX systems depending on absorption by the detector window, and they are only detectable with limited sensitivity by others.

Analysis by EDX represents a useful complementary approach to conventional imaging. Figure 5A shows an ADF image of a Cr-doped AlN film which shows room temperature ferromagnetic behavior. Since the contrast of an ADF image should be sensitive to the atomic number,  $Z$ , of the sample region

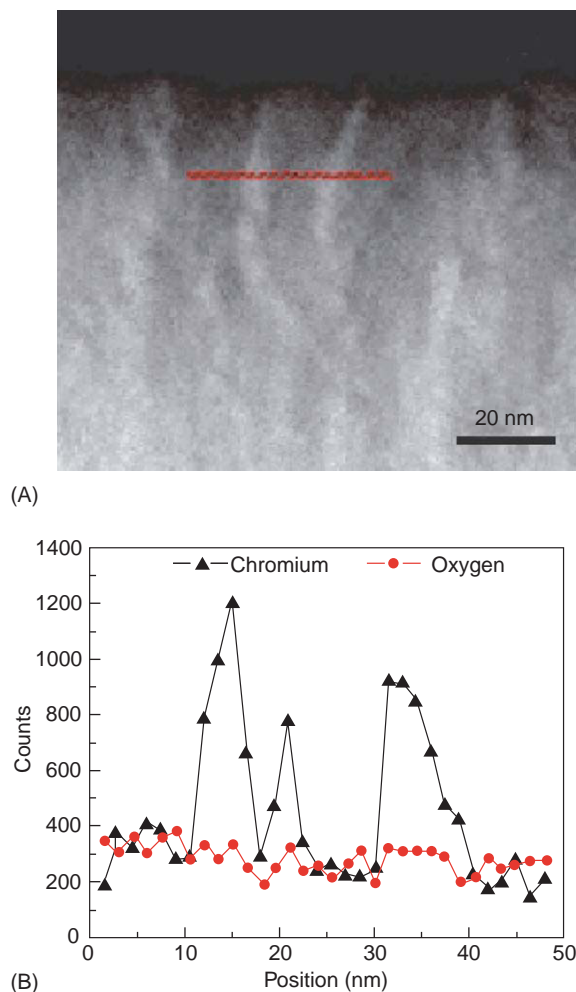

being imaged, the white, roughly columnar regions are interpreted as being Cr-rich. EDX spectra, as shown by the example in Figure 5B, were acquired with a small ( $\sim 0.5$  nm) focused probe. The Cr line profile shows that Cr has large upward and downward swings by factors of 2 or 3, indicative of Cr nanoclusters within the film. In contrast, the matching O profile is relatively flat, implying that no chromium-oxide phase had been formed either during deposition or postgrowth annealing.

## Advanced and Novel Approaches

### Electron Holography

Electron holography is an electron interference method that permits the retrieval of both the amplitude and the phase of the electron beam, unlike the case for normal image recording where all of the phase information is lost. A coherent source of electrons, usually provided by a field-emission electron gun, is a necessary requirement. Interference between the reference wave in vacuum and the wave that has passed through the specimen is then achieved using a thin, positively charged wire ('biprism') conveniently located in the imaging system, usually in the selected-area aperture plane. The electron wave present at the exit surface of the sample can be reconstructed, and high-spatial-resolution information about any internal electric and magnetic fields can then be extracted. The technique known as off-axis holography is most commonly used, and allows the mean inner potential of the sample to be accurately measured (to within  $\sim 1\%$ ). The technique is thus useful for studying interface sharpness and any diffusion across interfaces. Specimens should preferably be thin ( $< 200$  nm) in order to minimize inelastic scattering. Moreover, because of the need for a reference beam, the region of interest should typically be located no more than  $\sim 200$  nm from the edge of the specimen.

Knowledge of the electrostatic potential distributions across device junctions is of critical importance to design engineers. Typically, indirect methods such as dopant concentration profiling by secondary ion mass spectrometry, are used to extract relevant information, but the available spatial resolution is inadequate for current and future generation devices. A recent development of off-axis electron holography has been the demonstration that potential distributions within real devices can be imaged with high spatial resolution ( $\sim 6$  nm) and sensitivity ( $\sim \pm 0.1$  V). Figure 6 illustrates an application of the holographic technique to characterize the two-dimensional (2D) potential distribution within a deep submicron p-type field-effect transistor. Figure 6A

**Figure 5** (A) Cross-sectional ADF image of ferromagnetic Cr-doped AlN film; (B) corresponding EDX spectrum indicating presence of Cr-rich regions along line indicated in (A).

**Figure 6** (A) Off-axis electron hologram from a pMOS transistor device; (B) corresponding electrostatic potential. Contour steps of 0.1 V. Gate and source/drain (SD) contacts are indicated.

shows the original hologram and **Figure 6B** shows the reconstructed 2D map of the electrostatic potential within the device resulting from the B doping, where the phase contour steps correspond to 0.1 V. Further studies are still needed to determine whether changes in potential as a result of device biasing can be measured reliably, and there are concerns that need to be resolved about surface ‘dead layers’ sometimes caused during sample preparation. Nevertheless, it is already clear that the technique is likely to have a major impact on future device engineering.

### TEM Cathodoluminescence

CL in the TEM involves the collection and analysis of light that is emitted from a specimen when it has been excited by irradiation with the electron beam.

Whereas all specimens in a TEM will emit X-rays that are detectable by EDX, only those with an appropriate electronic structure, such as a suitable band-gap or energy states in ionic impurities, will emit light. In thin specimens, the CL signal may be too weak to be detected because there is limited material available to luminesce and the presence of surface states may reduce the CL intensity. Details of CL spectra can indicate the presence of electronic states associated with impurities and defects at the parts-per-million level and the distribution of such inhomogeneities can be mapped using the STEM mode. A major attraction of (S)TEM CL is its ability to correlate CL emission with microstructure and thus provide a direct link between electronic structure and crystalline defects. The CL spatial resolution is determined by the probe size and several factors that are specimen-dependent, including thickness, carrier diffusion length, CL generation volume and temperature: 200 nm is attainable in some materials. The technique can be used for detecting and mapping optically/electrically active dopants, impurities, and defects in semiconductors, especially direct band-gap (i.e., not silicon generally) and wide band-gap materials such as diamond, group III nitrides, and some minerals.

### Transmission Electron Microscopy

It has been shown here that the TEM, which has evolved over a period of more than 70 years into a highly sophisticated instrument for microstructural characterization, has many different operating modes that can be important in the field of semiconductor technology. As new types of device structures continue to be developed and as device dimensions are pushed ever smaller, these TEM-based techniques will remain at the forefront of developmental research. And it has been noted that electron holography is already starting to have an important role in submicron device engineering. As well as being applied to the characterization of fabricated materials and structures, the TEM is increasingly being used for studying growth of semiconducting materials in real time within the microscope, both under idealized ultrahigh-vacuum (UHV) conditions and also under less clean but perhaps more technologically relevant situations. Specialized UHV instruments remain the highly restricted domain of a comparatively few university and corporate research laboratories, but they will continue to be important because workers in the field are concerned to understand the properties and behavior of clean semiconductor surfaces. Under vacuum conditions more typical of recent fabrication procedures, the *in situ* imaging of nucleation

and growth of epitaxial layers on semiconductor surfaces, and the process of metallization within a controlled atmosphere environmental cell are exciting, and very promising, developments. Finally, electron microscopes will undoubtedly continue to be heavily utilized as an analytical and diagnostic tool for failure analysis in semiconductor laboratories.

## Introduction

Since the 1950s, transmission electron microscopy (TEM) has made a significant contribution to the study of biological materials at the cellular, subcellular, and macromolecular levels. From an essentially qualitative beginning, increasingly quantitative data have been obtained, limited in resolution primarily by the specimen preparation techniques and lability of biological molecules within the electron beam, rather than the instrumental resolution. It is the aim of this article to concentrate only on the macromolecular applications, with emphasis being placed on protein molecules, nucleic acids, and their interaction with proteins, membranes, lipids, and lipoprotein complexes. Apart from direct structural analysis, the use of immunolabeling at the molecular level has provided a major extension of the lower-resolution cellular and tissue-based antigenic localization, with immunoferritin or immunogold complexes. Individual protein subunits, subunit domains, and antigenic epitopes have been labeled with specific

immunoglobulins or Fab fragments, from either polyclonal or monoclonal antibodies. Indeed, chemical labels that incorporate nanogold clusters have enabled the position of thiol esters to be defined, for example, within the  $\alpha_2$ -macroglobulin molecule. These very small electron-dense labels are likely to provide further localization of specific sites within protein molecules in the future.

The study of macromolecular structure by scanning transmission electron microscopy (STEM) has, in general, not provided information beyond that already available from TEM. Nevertheless, the determination of the molecular mass by dark-field STEM from the electron scattering of unstained macromolecules, exploited throughout the 1980s by Andreas Engel and others, continues to provide useful comparative if not absolute data. Determination of the mass of the nuclear pore complex and its components has been a valuable contribution of this approach. The problem of varying mass loss with electron dose appears to necessitate extrapolation to zero dose for all biological samples. The introduction of protein stabilization by glutaraldehyde treatment, which is necessary in some cases, also introduces a variable that is difficult to standardize quantitatively. High-resolution scanning electron microscopy (SEM) has begun to make a contribution at the macromolecular level, but is unlikely to ever reach or exceed the resolution attainable by TEM.

and growth of epitaxial layers on semiconductor surfaces, and the process of metallization within a controlled atmosphere environmental cell are exciting, and very promising, developments. Finally, electron microscopes will undoubtedly continue to be heavily utilized as an analytical and diagnostic tool for failure analysis in semiconductor laboratories.

## Introduction

Since the 1950s, transmission electron microscopy (TEM) has made a significant contribution to the study of biological materials at the cellular, subcellular, and macromolecular levels. From an essentially qualitative beginning, increasingly quantitative data have been obtained, limited in resolution primarily by the specimen preparation techniques and lability of biological molecules within the electron beam, rather than the instrumental resolution. It is the aim of this article to concentrate only on the macromolecular applications, with emphasis being placed on protein molecules, nucleic acids, and their interaction with proteins, membranes, lipids, and lipoprotein complexes. Apart from direct structural analysis, the use of immunolabeling at the molecular level has provided a major extension of the lower-resolution cellular and tissue-based antigenic localization, with immunoferritin or immunogold complexes. Individual protein subunits, subunit domains, and antigenic epitopes have been labeled with specific

immunoglobulins or Fab fragments, from either polyclonal or monoclonal antibodies. Indeed, chemical labels that incorporate nanogold clusters have enabled the position of thiol esters to be defined, for example, within the  $\alpha_2$ -macroglobulin molecule. These very small electron-dense labels are likely to provide further localization of specific sites within protein molecules in the future.

The study of macromolecular structure by scanning transmission electron microscopy (STEM) has, in general, not provided information beyond that already available from TEM. Nevertheless, the determination of the molecular mass by dark-field STEM from the electron scattering of unstained macromolecules, exploited throughout the 1980s by Andreas Engel and others, continues to provide useful comparative if not absolute data. Determination of the mass of the nuclear pore complex and its components has been a valuable contribution of this approach. The problem of varying mass loss with electron dose appears to necessitate extrapolation to zero dose for all biological samples. The introduction of protein stabilization by glutaraldehyde treatment, which is necessary in some cases, also introduces a variable that is difficult to standardize quantitatively. High-resolution scanning electron microscopy (SEM) has begun to make a contribution at the macromolecular level, but is unlikely to ever reach or exceed the resolution attainable by TEM.

The correlation of molecular localization/labeling data with biochemical data of a structural nature is very important. Furthermore, it is pertinent that all TEM structural investigations on macromolecular material require a constant two-way interaction with the established biochemical, biophysical, molecular biological, physiological, microbiological, and immunological approaches. To obtain a meaningful understanding of nature, macromolecular structure must always be related to biological function.

## Sample Types

In general, it is essential that the macromolecules or membraneous organelles utilized for TEM studies of the type to be described should be isolated from tissues or single cells by subcellular fractionation procedures and subjected to centrifugal, chromatographic, and other techniques that are able to yield the highest possible homogeneity, purity, and stability in solution.

Having obtained homogeneity/purity, a range of electron microscopical specimen preparation techniques can be applied to organelle or membrane suspensions and solutions of macromolecules, which usually require only a few microliters of fluid

containing a protein/lipid/nucleic acid concentration in the range  $0.01\text{--}1.0\text{ mg ml}^{-1}$ . The presence of buffer salts, surfactants, and organic centrifugation materials such as sucrose, glycerol, and metrizamide can often create problems during specimen preparation and these should be removed, e.g., by centrifugal pelleting or filtration with washing, or dialysis against a low-molarity buffer, if possible. It is important that no dissociation or aggregation of the macromolecule(s) under study occurs in solution, as this can greatly interfere with specimen preparation, as well as subsequent image interpretation.

## Techniques

Several well-established and extensively documented techniques are available for the production of specimens of freely dispersed viruses, macromolecules, and cellular membranes. In all cases, it is important that the material is thinly spread in such a manner that individual particles can be defined with respect to their dimensions and shape, even though several different orientation-dependent image projections may be produced from a single particle by the TEM. Metal shadowing (single-angle and rotary) has been utilized for the production of specimens of nucleic acids,

**Table 3** Some applications of TEM to enzymes and soluble proteins

Acetyl-CoA carboxylase	Lectins and hemagglutinins
Acetylcholine esterase	Leucine aminopeptidase
Alcohol oxidase	Lipoproteins, apolipoproteins, lipoporphins, vitellogenins, yolk proteins, chylomicrons
Alkaline phosphatase	Lumazine synthase
Aminoacyl-tRNA synthetase complex	Lysozyme
5-Aminolaevulinate synthase	$\alpha_2$ -Macroglobulin
Annexins	$\alpha$ -Mannosidase
Apo ferritin and ferritin	Methanol dehydrogenase
Arginine decarboxylase	Methylreductase
L-Asparaginase	Multicatalytic proteinase/20S and 26S proteasome
L-Aspartate- $\beta$ -decarboxylase	Neuraminidase
Casein	Nitrogenase
Catalase	Papain
Chaperones and heat-shock proteins (GroEL/ES, cpn 60/10)	
Chaperone-protein complexes	Pepstatin A polymers
Citrate lyase	Phage head-tail connector
Citrate synthase	Phosphofructokinase
Clotting factors (factor V, factor VIII)	5-Phosphoribose-1-pyrophosphate synthetase
Complement proteins	Phosphorylase
Contortin	Phosphorylase kinase
C-Reactive protein	Phycobiliproteins
Creatine kinase	Phytohemagglutinin
Crotoxin	Propionyl-CoA carboxylase
$\alpha$ -Crystalin	Protein kinase
DNA (cytosine-5-) methyltransferase	Pyruvate dehydrogenase complex
DNA B oligomer	Pyruvate carboxylase
Echinonectin	rev Protein
Excinuclease	Reverse transcriptase
Fatty acid synthetase	Riboflavin synthase
Fibronectin receptor	D-Ribulose-1,5-bisphosphate carboxylase/oxygenase (RUBISCO)
$\beta$ -Galactosidase	Ribonucleases
$\beta$ -Glucuronidase	Ribonucleotide reductase
Glutamate dehydrogenase	Seed storage proteins
Glutamine synthetase	sn-Glycerol-3-phosphate-acyltransferase
Glycogen	Soluble Mg-ATPase complexes
Glycogen synthase/kinase	Starch granules
Gramicidin S synthetase	Sucrase/isomaltase
Hemoglobins, hemocyanins, erythrocytins	Thyroglobulin
Haptoglobins	Torin
Immunoglobulins	Toxins (cholera, <i>Staphylococcus aureus</i> , tetanus)
Inclusion-body proteins	Transcarboxylase
Insulin receptor	Tripeptidylpeptidase II
Invertase	Urease
$\alpha$ -Ketoacid dehydrogenase complex	

protein molecules, and membranes. The most satisfactory results have often been obtained directly following freeze-drying of the biological material from water or volatile buffer solutions (e.g., glycerol, ammonium acetate, ammonium hydrogencarbonate). Negative staining with heavy-metal-containing salts, established throughout the 1960s, continues to be one of the principal approaches used for inducing image contrast around thinly spread particulate material. This technique does have limitations with respect to image resolution ( $\sim 1.5$  nm), but because of its wide applicability and simplicity it continues to be a valuable approach. Superior resolution has been achieved,

under low electron dose conditions, using aurothio-glucose or glucose as the 'negative' stain. Recently the author has achieved considerable success using mixtures of negative stain and trehalose.

A technical variation of conventional negative staining, termed the negative staining-carbon film technique, was introduced by Ivonné Pasquali-Ronchetti and Robert Horne in the mid-1970s. Highly purified and concentrated ( $\sim 1\text{--}5$  mg ml $^{-1}$ ) virus or protein is mixed with ammonium molybdate and poly(ethylene glycol) (PEG) and spread on freshly cleaved mica. After air-drying, the material is carbon-coated *in vacuo*, and the layer of carbon plus

adsorbed protein is floated onto the surface of aqueous negative stain (e.g., uranyl acetate, ammonium molybdate, or even water, for rapid freezing/vitrification). This procedure has enabled the production of two-dimensional (2D) arrays/crystals of the virus particles and protein molecules. From the TEM images of such 2D crystals, image processing has produced averaged reconstructions of the projection (2D) images. The extension of this approach to 3D reconstruction, from a series of tilted images, has severe problems unless the protein molecules are totally surrounded by negative stain; apparently this is not often the case with 2D crystals prepared on mica. An alternative successful approach to protein crystallization has been the formation of crystals on lipid monolayers, followed by negative staining or vitrification. This has been particularly successful for the calcium-binding annexins. The high-resolution electron-crystallographic approach to the study of protein molecules, developed initially by Aaron Klug, Nigel Unwin, Richard Henderson, and others in Cambridge, UK, using tobacco mosaic virus, thin 3D crystals of bovine liver catalase, and the naturally occurring 2D crystal of bacteriorhodopsin in the purple membrane of *Halobacterium halobium*, has continued strongly in several parts of the world. High-resolution studies have been performed with experimentally produced 2D crystals of membrane proteins and thin 3D crystals of soluble protein, such as crotoxin. Integral membrane proteins have been crystallized after solubilization and purification in

the presence of neutral surfactants, usually followed by controlled removal of surfactant by dialysis or conventional salt or PEG crystallization, and replacement of the biological lipids. Considerable success has been achieved using this approach during the study of *Escherichia coli* PhoE porin by Bing Jap in Berkeley and for the chloroplast light-harvesting complex by Werner Kühlbrandt in Heidelberg. The use of spot-scan imaging of crystalline specimens has been introduced to reduce the electron beam-induced radiation damage and specimen mobility while performing photographic image recording, thereby leading to superior resolution.

In parallel with the crystal studies, procedures for single-particle classification and structural analysis have been developed by Joachim Frank, Marin van Heel, and others, with which considerable progress has been made. A good example of this approach is the understanding of ribosome structure, which has led to the localization of individual ribosomal proteins and RNA within this important biological particle. The production of unstained vitrified/frozen-hydrated specimens of a wide range of biological materials, pioneered by Jacques Dubochet and his colleagues in Lausanne, has now become a widely used technique, which maintains the hydration state of the biological material and avoids the interaction with heavy-metal stains. The resolution obtainable from vitrified specimens is usually not greatly superior to that from negative staining. The two techniques tend to provide images that are very much in agreement, but vitrification has greater possibilities for the study of dynamic biological systems, such as microtubule formation and disassembly, actin–myosin interactions, and calcium-induced structural changes in gap junction channels.

## Applications

In view of the extremely large number of current applications of TEM to the study of isolated biological materials, quite apart from the extensive tissue-based ultrastructural studies, only a very limited number of examples can be presented, and, for brevity, several other significant applications are tabulated (Tables 1–4). Individual animal, plant, and bacterial viruses are not listed, because of the accepted applicability of TEM to the analysis of viral structure; some references to the viral literature are, however, included in the Further Reading section.

Examples of the application of TEM to the study of respiratory proteins are shown in Figures 1 and 2. The first example (Figure 1A) of negatively stained key-hold limpet (*Megathura crenulata*) hemocyanin (KLH) shows a 2D crystal of the side-on image

projection of this giant cylindrical protein (the didecamer; relative molecular mass  $\sim 7$  MDa) produced by the negative staining–carbon film procedure. The crystallographically averaged 2D reconstruction of this image projection has been obtained by computer processing (Figure 1B). The KLH didecamer has a fivefold rotational symmetry, which tends to interfere with formation of 2D crystals when the cylindrical molecule is orientated end-on. Nevertheless, an averaged reconstructed image can be obtained by single-particle analysis (Figure 1C).

Annelid hemoglobin is also a giant macromolecular assembly, with a relative molecular mass of  $\sim 3$  MDa. Extensive negative staining studies have been performed on this macromolecule, which tend to reveal the same type of stable orientations of the

molecule (side-on/end-on) and image projections as with KLH. However, when preserved unstained in vitreous ice (Figure 2A) the hemoglobin presents a greater range of intermediate images, because of the freely varying rotational angles of the molecule relative to the electron beam, within the surrounding ice. From computer classification and image processing of these different 2D images, a single-particle 3D reconstruction has been obtained (Figure 2B).

Application of the negative staining–carbon film procedure to the much smaller human erythrocyte catalase (relative molecular mass 256 kDa) has resulted in the formation of several different paracrystalline and truly crystalline 2D forms, an occurrence also encountered with the *E. coli* chaperone GroEL. One of the catalase 2D crystal forms is

**Figure 1** (A) A 2D crystal of keyhole limpet haemocyanin (KLH) (didecamer) with molecules orientated side-on, produced by the negative staining–carbon film procedure. Bar = 50 nm. (B) The reconstructed 2D image of KLH produced by crystallographic image processing, without symmetrization. (C) The reconstructed 2D image of the end-on KLH molecule, produced by single molecule averaging (without symmetrization). The fivefold rotational symmetry of the molecule is apparent. **Figure 2** (A) A noisy transmission electron micrograph of vitrified earthworm hemoglobin and (B) the 3D single particle reconstruction produced with the IMAGIC-5 image processing software. Note in (A) the faint images of the hemoglobin molecules at different orientations within the vitreous ice, due to varying molecular rotation with respect to the axis of the electron beam. (Micrographs kindly provided by Dr. Marin van Heel, Fritz-Haber Institute, Berlin.)

**Figure 3** Two-dimensional crystals of human erythrocyte catalase, produced by the negative staining–carbon film procedure. These crystals possess a  $p22_12_1$  symmetry. Note the group of free molecules, the line of dislocation (between arrow heads), and the occasional absence of molecules within the crystal lattice. Bar 100 nm. Compare with the crystallographic 2D color image reconstruction shown in Figure 4, which emphasizes the four-molecular row repeat across the crystal lattice. Image processing was performed with the assistance of S. Volker and Dr. H. Engelhardt, Max-Planck-Institute for Biochemistry, Martinsried, Germany, using the Semper software system. (Modified from Harris JR *et al.* (1993) *Journal of Structural Biology* 111: 22–33.)

**Figure 4** The crystallographic reconstruction produced by image processing from the  $p20$  2D crystal form of human erythrocyte catalase shown in Figure 3. Protein is denoted by green, light blue, and yellow. Negative stain (uranyl acetate) is represented by red and dark blue, with dark blue for the regions of deepest stain. Note the four-row repeat across the crystal lattice, due to highly specific molecular orientation within the 2D crystal. (Reproduced with permission of Harris JR, Johannes Gutenberg-Universität Mainz, Germany.)

shown in Figure 3; the corresponding crystallographic image reconstruction is illustrated in Figure 4. The phenomenon of 2D crystal and paracrystal diversity should be considered perfectly normal, since it is known that many proteins produce multiple 3D crystal forms. The future study of 2D and

3D protein associations, crystal nucleation, and subsequent crystal formation during the negative staining–carbon film procedure would appear to hold considerable potential.

Although many studies on DNA and DNA–protein interaction have utilized metal shadowing to produce bright-field image contrast, dark-field TEM (annular or spectroscopic) of unstained or uranyl acetate-stained and metal-shadowed nucleic acid–protein complexes also provides useful resolution. In **Figure 5**, a short length of DNA (2356 base pairs), with attached progesterone receptor, is revealed by dark-field TEM. The RecA protein has the ability to

**Figure 5** DNA (2356 base pairs long), representing the regulating region of the uteroglobin gene, and containing two hormone-responsive elements (HREs). Two closely apposed progesterone receptors are bound to these HREs, separated by 260 base pairs, giving rise to a DNA loop (arrow head) due to the interaction between the two receptors. Bar = 50 nm. The DNA–protein image was produced by annular dark-field TEM. (The electron micrograph was taken by A. Barbin and kindly provided by Dr. E. Delain, CNRS and Institute Gustave-Roussy, Villejuif, France.)

complex with single- and double-stranded DNA, to produce an organized linear array of the RecA on the DNA. Such complexes have been revealed by negative staining, metal shadowing, and in the unstained frozen–hydrated state by vitrification. In **Figure 6**,

**Figure 7** Part of a large paracrystalline aggregate of *Xenopus* lamin-A, expressed in *E. coli*. Note the characteristic 25 nm periodicity along the filamentous aggregate. Bar = 0.5  $\mu$ m. (The sample material was kindly provided by Gieffers C and Krohne G and the specimen was produced from a solution of protein in 2 mol l<sup>-1</sup> ammonium acetate by the negative staining–carbon film procedure.)

**Figure 6** A comparison of the rendered surfaces of TEM reconstructions of the active RecA–DNA filament (left) and the inactive RecA–DNA filament (right) with the RecA crystal surface (center). The RecA crystal surface, obtained by X-ray crystallography, has been rendered at low resolution, to be comparable with the TEM reconstructions. Both the active and inactive filament reconstructions are from averages of frozen–hydrated specimens imaged with cryo-EM. (B) A partly purified nuclear pore complex fraction obtained by Triton X-100 extraction and ultrasonication of nuclear envelope, followed by sucrose density gradient centrifugation. Bars = 200 nm.

**Figure 9** The  $P\beta'$  phase of bovine brain sphingomyelin revealed by negative staining with uranyl acetate on (A) a multilamellar body and (B) a single bilayer. Liposome particles are present on the surface of the larger lipid bilayer structures. Bars = 100 nm. (Reproduced with permission from Harris JR (1986) *Micron and Microscopica Acta* 17: 175–200.)

reconstructed rendered surfaces obtained by image processing from vitrified specimens of the active RecA–DNA filament and the inactive RecA–DNA filament are compared with the RecA crystal data.

The filamentous lamin proteins, in a manner similar to collagen,  $\alpha$ -tropomyosin, and intermediate

filament fragments, have the ability to form linear multimolecular paracrystalline aggregates by treatment under appropriate ionic conditions *in vitro*. These aggregates exhibit characteristic periodicities determined by the specific intermolecular interactions and repeating linear overlap of the extended peptide chains. One such example of a paracrystal of

bacterially expressed lamin A that possesses ~25 nm periodicity is shown in **Figure 7**.

TEM has contributed to the understanding of the structure of many bacterial cell wall and eukaryotic cellular membrane systems, *in situ* and after isolation as purified subcellular fractions. The nuclear envelope, with its integral and ubiquitous pore complexes, has received much attention over a period of many years. Useful data have been obtained from all the available specimen preparation techniques, including vitrification, from which detailed models of the nuclear pore complex have been presented in recent years. In addition, high-resolution SEM has provided supplementary data that has extended the interpretation available from TEM alone. The functional role of the nuclear pore complex in translocation of proteins and ribonucleoproteins to and from the nucleus is currently being actively addressed using ultrastructural as well as cell-biological approaches. An example of nuclear envelope, isolated from rat liver by biochemical treatments and centrifugation procedures, and subjected to negative staining, is shown in **Figure 8A**. The ~100 nm outer annuli of the nuclear pore complexes are revealed with great clarity, but it is likely that this type of isolated material has been subjected to some morphological disruption during the isolation steps and has been flattened to some extent by the specimen preparation procedure. Nuclear pore complexes extracted by neutral surfactant and ultrasonication and partly purified by density gradient centrifugation are shown in **Figure 8B**. The ultimate goal of producing the nuclear pore complex as an 'intact' and highly purified macromolecular assembly, by biochemical subfractionation of the nuclear envelope, has recently been achieved and valuable information on its subcomponents has already emerged, particularly from the studies of Ueli Aebi, in Basel. In addition, an *in vitro* system for nuclear envelope and nuclear pore complex formation has recently become available.

Aqueous liposomal and micellar suspensions of phospholipid have been studied by TEM for a number of years. The characterization of the single and multiple lipid bilayer nature of liposome particles was greatly assisted by early negative staining TEM studies and was supported by freeze-fracture analysis. In recent years, vitrified specimens have also been produced, which avoid the problems of liposome-stain interaction and distortion (flattening) that may be present in the negatively stained specimens. The study of lipid phase changes and the dynamic membrane fusion event in liposome and reconstituted lipid-protein membrane systems can be studied with some degree of accuracy by TEM. The former (a relatively slow event) can be studied

by freeze-fracture and negative staining, but the latter cannot; it is in the area of lipid bilayer fusion that vitrification of unstained liposomes has made a significant contribution. An example of the undulatory P $\beta$ ' phase of sphingomyelin is shown in **Figure 9**. The production and removal of this lipid phase with

**Figure 10** Reconstructions of Blue tongue virus (BTV) and core-like particle obtained from frozen-hydrated specimens. (A) The surface representation of the outer shell of the reconstructed virus particle viewed along a threefold axis. The globular regions (VP5) are colored yellow and the sail-shaped spikes (VP2) are blue. Bars = 10 nm. (Reproduced from Hewat EA, Booth TF, and Roy P (1992) *Journal of Structural Biology* 109: 61–69.) (B) The surface representation of the BTV core-like particle viewed down a threefold axis from outside the particle. Bar = nm. increasing temperature has been studied by incubating the lipid suspension and preparing the negatively stained specimens under carefully controlled conditions of incremental temperature.

As the discussion throughout this article has essentially neglected reference to the vast body of important data relating to viral structure, and because there is no separate article within the present Encyclopedia devoted to the analysis of viral structure, an example of the application of TEM to the study of frozen-hydrated Blue tongue virus is given in the color plate section. As with the other areas of biomolecular TEM application discussed above, large contributions to the knowledge of viral particles have come from negative staining and metal shadowing, data that are currently being essentially confirmed and extended by the use of frozen-hydrated/vitrified specimens. It should also be emphasized that conventional thin sectioning of cells and tissues for TEM has made a major contribution to the study of viral morphogenesis, structure, cellular infection, and release (Figure 10).

## Introduction

There are several basic types of light microscopes, each appropriate to a particular application. The basic function of a microscope to study the structure of a specimen can be extended to a range of analytical functions. These include measurement and image analysis, and by using techniques such

as histochemical staining, the identification and localization of specific chemical components. With appropriate preparations, living processes can be studied and recorded. A temperature-controlled stage may be used to study temperature-dependent changes such as melting or freezing, and, with the addition of differential scanning calorimetry (DSC), energy changes associated with the chemical or physical changes can be directly related to the observed structures.

## Simple Microscope

At its simplest, the microscope is a single lens, consisting of a single glass component, or several components cemented together to reduce spherical and chromatic aberrations. It is generally used as a hand lens for low-magnification examination. Alternatively, the lens may be mounted on a simple stand to free the user's hands for various purposes (e.g., for dissection). Such instruments are cheap and simple, but suffer from the twin disadvantages of low magnification (up to  $25\times$ ) and the fact that they must be brought very close to the eye to achieve a satisfactorily large field of view. All other microscope types achieve higher magnifications and greater ease of use by applying lenses in combination (objective and eyepiece lenses) to give a compound microscope.

## Stereomicroscope

A stereomicroscope, sometimes called a dissecting microscope or a binocular inspection microscope, is a low-power compound instrument used for a closer examination of three-dimensional specimens than is possible with a hand lens (**Figure 1**). It gives a high-quality image with a full three-dimensional effect, produced by viewing the specimen with both eyes from slightly different viewpoints. It usually has a considerable depth of field and a long working distance, giving easy mechanical interaction with the specimen. There is no lateral reversal of the image as with most other compound microscopes, i.e., the image is upright, enabling spatial relationships within the specimen to be easily appreciated.

Many early stereomicroscopes were of the twin-objective or Greenough type, having quite separate optical systems for each eye. Because of the restricted field of view in focus at any one time in that system, it has been largely superseded by instruments having a common large main objective lens, with separate lens systems mounted above for each eye. Older instruments of this type may have a rotating turret of objectives of fixed magnification, whilst most new

**Figure 1** A modern zoom stereomicroscope, for observation of samples in incident light. (Courtesy of Olympus UK Ltd., used by permission.)

examples have a continual adjustment of magnification or zoom lens. Current top-of-the-range instruments may also offer other illumination facilities such as dark field. Available overall magnification is typically up to about  $50\times$ , although common main objective lenses can be replaced with more powerful ones to give overall magnifications of  $100\times$  or more, at the cost of a much reduced working distance and depth of field. The main disadvantage of the common main objective design is that the numerical aperture of the system is limited by the presence of the double beam path above. This has led to the development of the 'macroscope', an instrument with a large diameter objective giving a greatly improved numerical aperture. An alternative solution, which loses the three-dimensional effect of the stereomicroscope, is the 'deep-field microscope' described later.

## Compound Microscope

The transmitted-light compound microscope was first developed for use by biologists, and this remains main use of the microscope, although there are also many applications in fields such as mineralogy, crystallography, and materials science. Because light

is transmitted through the specimen, this is necessarily relatively thin, and thin sections mounted on a glass slide with a coverslip are used for most applications.

### General Arrangement

There are many variations in microscope design but the basic components are usually the same (**Figure 2**). The microscope stand carries a stage at right angles to the optical axis, a tube carrying the objective lenses and eyepieces, and an illumination system consisting of a condenser and a lamp. The parts may be arranged in different ways on different models.

Most modern microscopes are binocular, meaning that the 'same' image is seen by both eyes, reducing user fatigue. Whilst early microscopes had the optical axis tilted toward the user, the optical axis is now normally arranged vertically, with prisms beneath the eyepieces to enable them to be tilted to provide a comfortable viewing angle. Many microscopes also provide an extra tube for the attachment of a camera.

The objective lenses are usually carried on a rotating nosepiece that holds several lenses. Most

objectives for modern microscopes are multielement assemblies, and are designed to correct chromatic aberrations by bringing different colors (wavelengths) to a common focus. Plano-objectives or 'flat field' objectives also compensate for field curvature, bringing the whole field of view into focus; this again reduces user fatigue. Objectives from the same manufacturer should normally be parfocal, i.e., focus at the same position. They are normally designed to work with 0.17 mm thick glass coverslips; any other coverslip thickness may result in some aberration of the image. Lower-magnification objectives are designed to work 'dry', with air between the objective and coverslip. Higher-magnification objectives – marked 'OIL', 'OEL', or 'HI' (homogeneous immersion) – are designed to work with immersion oil of a specific refractive index between lens and coverslip.

Whilst earlier microscopes used an adjustable mirror to reflect light from an external source into the optical axis of the microscope, modern instruments have a built-in lamphouse. The light is focused on the object plane by means of a condenser, an assembly of lenses that matches the light beam to the numerical aperture of the objective.

The microscope stage carries an object slide with provision for holding the slide in place. On earlier microscopes the stage was fixed and the microscope tube was moved up and down to focus the image. More recently, the microscope tube is generally fixed to the stand and the stage is moved up and down. However, both arrangements (fixed and moving stage) are in use.

A specialized form of the transmitted-light compound microscope is the 'inverted microscope' (**Figure 3**), used for objects such as cell cultures, in which the microscope tube and optics are mounted below the specimen, which in turn is illuminated from above. A prism is used to incline the eyepieces at a comfortable viewing angle. Another specialized form is the 'portable microscope', of which the McArthur instrument is the best known. These allow a compound microscope to be taken out into the field.

### Illumination Methods

The conventional transmitted-light compound microscope uses a bright-field system, in which the condenser gives a bright, even illumination across the whole of the field of view. This form of illumination, when correctly set up, is ideal for the examination of a wide range of specimens, particularly stained thin sections of biological material. Where there are no natural variations in color or optical density of the

**Figure 2** A upright transmitted-light compound microscope with binocular eyepieces and an illuminator for epi-fluorescence. (Courtesy of Olympus UK Ltd., used by permission.)

**Figure 3** An transmitted-light inverted microscope. (Courtesy of Olympus UK Ltd., used by permission.)

specimen, and where staining methods cannot be used, for instance with live preparations, other means must be used to impart some form of contrast to the image.

Dark-field or dark-ground illumination is used for objects with low contrast in bright-field illumination and renders images showing a bright specimen against a dark background. The specimen is illuminated with a hollow cone of light that cannot enter the objective lens. The image is formed by light that is diffracted or otherwise scattered by the object, which therefore appears in reverse contrast. This method has largely been replaced by phase-contrast microscopy for weakly scattering objects.

Phase-contrast microscopy was developed to observe living cells without the need for the normal fixing, mounting, and staining procedures that would kill them. Under bright-field illumination, living cells cannot easily be differentiated from the surrounding liquid, because the refractive indices of cells and water are very similar. Phase-contrast microscopes render these unstained cells visible with enhanced contrast of internal details using special objectives with annular phase plates. The condenser also has a series of annular diaphragms, each matched to the phase plate of a particular objective. The phase plate

produces a quarter-wavelength ( $90^\circ$ ) shift of phase. For best contrast, this wavelength must be defined, and so a color filter is often used. The color chosen is normally green, since this lies in the middle of the visible spectrum and hence the optimum wavelength for both the human eye and the microscope optics. Direct light is separated from diffracted light, producing interference and resulting in a dark image on a bright background or vice versa. The dark image on a bright background, known as dark or positive contrast, is used for the observation of the internal cell structure. Phase contrast often gives rise to a 'halo' around features of varying contrast in the image.

Another system for examination of low-contrast objects such as living cells is the Nomarski or differential interference contrast system. It is also particularly useful for materials that cannot be stained satisfactorily for other reasons, such as very thin sections that take up too little stain. This system employs polarizing filters and quartz prisms instead of the annular diaphragm and phase plates used in phase contrast. This eliminates the halo effect seen in phase contrast, rendering sharply defined images with good contrast, having a characteristically (pseudo) three-dimensional appearance. It is rather less suited to routine work than phase contrast however, and is considerably more expensive.

An extremely powerful analytical tool in light microscopy is observation of the specimen in polarized light, in which a piece of polaroid material, called a polarizer, is placed in the illumination path. Light waves vibrate at all planes at right angles to the direction of the ray. Polaroid material will pass only those rays vibrating in one plane at right angles to their direction. If a polarizer made of this material is placed in the light path before the specimen, most specimens will simply appear less bright. If a second piece of polaroid material, called the analyzer, is placed in the light path after the specimen and at right angles to the polarizer, the field of view will appear black except where the specimen has the ability to change the plane of vibration of the light. The specimen is then said to be viewed 'between crossed polars'. This is a property of most, but not all, crystalline materials. Some materials that are not normally thought of as crystalline, including many biological materials, plastics, and liquids (liquid crystals) also display this property. Some samples may produce a range of colors, known as birefringence colors, which can be important clues to the identity of many plastics, fibers, and minerals. It is usual for the analyzer to be mounted in a slide that can be pushed into or out of the light path but for the polarizer to be mounted so that it can be turned through an angle of more than  $90^\circ$ , so that the

changing effects can be observed. A polarizing microscope is also usually fitted with a rotating stage calibrated in degrees to allow the specimen itself to be rotated in relation to the angle of the polarizer and analyzer.

A development of the use of polarized light is the differential staining objective, which is used to impart optical colors to specimens mounted in a liquid of slightly different refractive index. Some specimens, including some artificial fibers and mineral fibers such as asbestos, have different refractive indices at different orientations to the plane of polarized light.

All the illumination methods discussed above are based on transmitted illumination, in which the light passes through the specimen from one side to the other. The alternative to this is incident-light (or epi-) illumination, in which the light passes down the objective before being reflected back through the objective to the eyepieces. Hence, no separate condenser system is required, and the illuminating light beam is always perfectly matched to the objective. These instruments are necessary for the examination of necessary opaque specimens and therefore are chiefly used in materials science, but there are increasing numbers of biological applications, such as the examination of leaf surfaces. The light beam enters the microscope at right angles to the optical axis and is turned through 90° using a dichroic mirror mounted at 45° to the optical axis. The objectives of these microscopes are designed for use on uncovered surfaces, i.e., without coverslip correction. Incident illumination is sometimes combined with the use of polarized light. A particular application of this is the observation of silver grains in autoradiographs, in which only the light reflected from the silver grains is seen against a dark background: the light reflected can be measured using a photometer and related to the number of silver grains present. A similar approach can be used with immunogold-labeled preparations.

The form of incident illumination most widely used in biological applications is fluorescence microscopy, in which light of a relatively short wavelength, often ultraviolet (UV) light, is passed down the objective and excites fluorescence at a longer wavelength in the specimen.

A recent and very sophisticated development of incident illumination is the confocal laser scanning microscope, in which a laser beam is scanned through the specimen, focused at varying depths within it. The signal obtained from the specimen is used to build up a picture on a computer monitor of an 'optical section' at a given depth. A three-dimensional reconstruction of a relatively thin specimen can be built up on the monitor to study variations in structure through its thickness.

## **Analysis Using Light Microscopes**

### **Measurement of Size, Area, and Distribution**

The magnification achieved by the microscope can be calculated accurately and linear measurements can be made by calibrating a graduated scale in the microscope eyepiece against a measurement scale marked on a microscope slide (a stage micrometer). With a camera mounted on the microscope, more complex measurements can be made on the photographs obtained. However, the fitting of a camera to the microscope and subsequent digitization of the image has led to the development of a wide range of image analysis equipment and software for the assessment of the image obtained.

A wide range of parameters can be assessed, including the lengths, widths, areas, and distributions of specific features. Once digitized, the image can be computer enhanced to aid its interpretation and analysis. The measurement of the brightness of light transmitted through the specimen (photometry) or the degree to which density of the specimen or a stain used to color it obscures the light (densitometry) can be used to assess the numbers of particular features in the field of view. Particle size analysis can also be carried out to give a size distribution curve.

### **Chemical Reactions and Structural Changes**

A temperature-controlled stage can be used to study the behavior of specimens at different temperatures or to measure and observe melting or freezing points. A modified version of such a stage allows the combination of microscopy with DSC to relate energy changes in the sample to visual changes such as starch gelatinization or the change of crystal states in fats.

### **Histochemistry**

An important application of the light microscope in biological work is the identification and localization of particular chemical species in microscope sections by the use of histochemical stains. More recently, fluorescent stains have been developed that are highly specific.

### **Confocal Microscopy**

Confocal scanning laser microscopy has been combined with the use of fluorescent stains to measure the distribution and concentration of specific analytes within biological tissue. Stains are used to bind selectively with the analyte under study, and the correct laser beam is selected to excite the stain used to give a fluorescent signal. The technique can also be

used to measure the thickness of translucent layers in a sample such as the enamel layer on teeth.

### Refractive Index Measurement

The refractive indices of glasses, minerals, plastics, and many other samples may be measured by a range of microscopical methods. The simplest of these is the examination of samples mounted in a range of liquids of which the refractive index is known until the sample-liquid interface becomes invisible. A development of this method involves the use of a microscope hot stage to raise the temperature of the liquid and sample gradually. Because in general the refractive index of the sample changes more slowly than that of the liquid as the temperature rises, a specific 'match temperature' can be determined. Either of these methods can be aided by observation of the Becke line, a bright fringe that appears just inside or outside the boundary of the fragment when it is almost in focus. The Becke line appears to move toward the medium of higher refractive index when the distance between specimen and objective is increased, thus indicating whether the mounting liquid has a higher or lower refractive index than the fragment.

## Other Microscopes

### Deep-Field Microscopes

One of the major limitations of conventional light microscopy is the characteristically shallow depth of the field, so that only a limited plane can be observed at one time. The depth of field can be extended by decreasing the lens aperture, but this results in loss of resolution and too little light passing through. This problem is overcome in the deep field microscope, often known as a video microscope, by applying an adjustable beam of highly intense light to the area under illumination. The object is observed using a subminiature color camera held between the fingers like a pencil torch. The achievable depth of field is extended further using two objective lenses, one of which is used to magnify while the other is free to focus the image on the second lens from a long working distance. The image is viewed on a TV monitor. The result is comparable with the depth of field provided by the scanning electron microscope.

### Laser Doppler Microscopy

The laser Doppler microscope is a development of the fluorescence microscope designed to enable the rate of movement of particles to be measured in

living specimens, using a laser beam to provide epi-illumination through the objective lens. The laser light is scattered by moving particles, the angle of scattering depending on particle size, the viscosity of the matrix surrounding the particles, and temperature. When the original laser frequency is mixed with the scattered frequency, a beat frequency is obtained for uniform motion of particles, and a characteristic spectrum of frequency for random Brownian motion. The technique has been applied successfully to the measurement of plastid movement in plant phloem sieve tubes.

### Ultraviolet Microscopy

Examination of specimens in UV light requires the use of optical components capable of transmitting such short wavelengths, which means the use of quartz rather than glass lens components. However, when combined with a UV spectrophotometer, this enables the analysis of small areas of a sample by UV reflectance, absorption, or transmission. An example of this is the identification of materials used by the artist in a painting. The use of UV microscopy for enhanced resolution has been entirely superseded by transmission electron microscopy.

### Infrared Microscopy

The infrared spectra of many organic materials reveal much important information about their chemical nature. The complex waveform produced by passing an infrared beam through a sample or collecting it from the sample may be analyzed by a Fourier transform to reconstruct all the waves that make up the waveform (FTIR microscopy). This enables experimental data to be compared with spectra from known standards. Thus, small amounts of a vast range of organic materials, from plastics through natural polymers to drugs, can be analyzed. The wavelength range of infrared radiation means that the theoretical resolution of an FTIR microscope is of the order of a micrometer, somewhat poorer than that of a visible-light microscope. However, modern instruments are capable of analyzing 10–20  $\mu\text{m}$  wide areas. Most work has been in transmission, but measurements with epi-illumination are now possible, simplifying specimen preparation. Infrared microscopes have also been used to measure the temperature of samples, and scanning versions have been built to enable maps of temperature distribution.

This article is a revision of the previous-edition article by P J Evennett and C Hammond, pp. 3127–3134, © 1995, Elsevier Ltd.

## Introduction

In this article, the range of specimen preparation techniques is surveyed and classified to provide the reader with an appreciation of the 'context' within which specimen preparation techniques are selected and carried out. However, it cannot provide a solution, or specific information, on the preparation technique for any 'particular' material or sample. Successful specimen preparation, in the end, depends on the judgment, experience, and experimental skill of the preparer, and each individual specimen may present its own particular problems; hence, there may be as many preparation techniques as there are materials or samples to be prepared.

First, the overall criteria for specimen preparation techniques are set down and discussed; these provide the basis on which all the subsequent techniques should be assessed. These fall into two main categories: those for transmitted light and those for reflected light.

Techniques for transmitted light are of major concern in biological light microscopy. This includes the techniques applying to living specimens, the preparation of permanent mounts of dead specimens, and fixation, dehydration and embedding, sectioning, and staining. Staining is a vast topic in its own right and the great variety of stains and staining techniques can only be touched on. The transmitted-light techniques for nonbiological materials (fiber particulates, soils, etc., and petrological thin sections) are also considered; to a certain extent these overlap biological preparation techniques (e.g., cutting polymer thin sections) and reflected-light surface preparation techniques (e.g., preparation of petrological thin sections). Finally, mounting techniques are

discussed in relation to their importance with respect to the microscope imaging system.

Reflected-light techniques for the preparation of 'bulk' specimens are simpler to consider and are confined largely to unmounted biological specimens and nonbiological materials (ceramics, ores, rocks, metals). For the nonbiological specimens there are three main stages. First, there is the process of mounting the specimen in a block to facilitate handling and to ensure that the prepared surface is flat without 'rounded' edges; then follows the initial preparation, grinding, lapping, and polishing, the object of which is to obtain a perfectly flat surface without distortion or obliteration (smearing) of the underlying structure. Finally, surface treatments that are almost invariably required in order to reveal the underlying structure are considered. Under this section come all the etching, electrolytic, and thin-film deposition treatments. This topic is analogous to that of staining of biological materials, and the range of etchants, electrolytes, and deposition techniques can only be touched on.

## Criteria for Specimen Preparation Techniques

The objective of specimen preparation for light microscopy is to allow the structures of materials (biological and nonbiological) to be revealed with sufficient contrast, and features of interest to be described, recorded, and characterized, at a fineness of scale beyond the visual acuity of the naked eye. The fineness of scale is ultimately limited by the limit of resolution (resolving power) of the microscope imaging system.

Hence, specimen preparation techniques and procedures should fulfill, as necessary and appropriate, the following five criteria:

1. They should ensure that the specimen to be examined is a representative sample of the (bulk) material, object, or organism that is to be investigated.

## Introduction

In this article, the range of specimen preparation techniques is surveyed and classified to provide the reader with an appreciation of the 'context' within which specimen preparation techniques are selected and carried out. However, it cannot provide a solution, or specific information, on the preparation technique for any 'particular' material or sample. Successful specimen preparation, in the end, depends on the judgment, experience, and experimental skill of the preparer, and each individual specimen may present its own particular problems; hence, there may be as many preparation techniques as there are materials or samples to be prepared.

First, the overall criteria for specimen preparation techniques are set down and discussed; these provide the basis on which all the subsequent techniques should be assessed. These fall into two main categories: those for transmitted light and those for reflected light.

Techniques for transmitted light are of major concern in biological light microscopy. This includes the techniques applying to living specimens, the preparation of permanent mounts of dead specimens, and fixation, dehydration and embedding, sectioning, and staining. Staining is a vast topic in its own right and the great variety of stains and staining techniques can only be touched on. The transmitted-light techniques for nonbiological materials (fiber particulates, soils, etc., and petrological thin sections) are also considered; to a certain extent these overlap biological preparation techniques (e.g., cutting polymer thin sections) and reflected-light surface preparation techniques (e.g., preparation of petrological thin sections). Finally, mounting techniques are

discussed in relation to their importance with respect to the microscope imaging system.

Reflected-light techniques for the preparation of 'bulk' specimens are simpler to consider and are confined largely to unmounted biological specimens and nonbiological materials (ceramics, ores, rocks, metals). For the nonbiological specimens there are three main stages. First, there is the process of mounting the specimen in a block to facilitate handling and to ensure that the prepared surface is flat without 'rounded' edges; then follows the initial preparation, grinding, lapping, and polishing, the object of which is to obtain a perfectly flat surface without distortion or obliteration (smearing) of the underlying structure. Finally, surface treatments that are almost invariably required in order to reveal the underlying structure are considered. Under this section come all the etching, electrolytic, and thin-film deposition treatments. This topic is analogous to that of staining of biological materials, and the range of etchants, electrolytes, and deposition techniques can only be touched on.

## Criteria for Specimen Preparation Techniques

The objective of specimen preparation for light microscopy is to allow the structures of materials (biological and nonbiological) to be revealed with sufficient contrast, and features of interest to be described, recorded, and characterized, at a fineness of scale beyond the visual acuity of the naked eye. The fineness of scale is ultimately limited by the limit of resolution (resolving power) of the microscope imaging system.

Hence, specimen preparation techniques and procedures should fulfill, as necessary and appropriate, the following five criteria:

1. They should ensure that the specimen to be examined is a representative sample of the (bulk) material, object, or organism that is to be investigated.

2. They should be such as to make the features of interest accessible to the microscope imaging system.
3. They should, where necessary, enhance the contrast between the structural elements of materials and between the structural elements and the undifferentiated background, such that the features of interest may be identified and recorded.
4. They should provide sufficient conditions for specimen stability, and sufficient means to protect the specimen from decay, degradation, corrosion, or contamination within the observational time scale.
5. They should match the specimen to the optical requirements of the microscope imaging system so as to provide the optimum conditions for image contrast and resolution and to avoid optical artifacts that may otherwise arise and that may obscure, or incorporate false detail into, the image.

The particular preparation techniques and procedures relating to these five criteria are summarized below and further details, and their importance with respect to different materials and scientific and technological disciplines, are set out in the subsequent sections.

Specimen preparation may be broadly classified into two main areas: specimen preparation techniques for transmitted-light microscopy (thin sections, smears, fibers, particulate strews) and specimen preparation techniques for reflected-light microscopy (surface preparation of opaque and nearly opaque materials). However, they are by no means exclusive and, although metals, ores, and opaque minerals may be studied by reflected light only, thin sections, smears, etc., may be studied both by transmitted and by reflected light, e.g., transmitted-light and epifluorescence microscopy. The advantages of such dual observational techniques relate in particular to contrast enhancement (criterion (3)).

It is important that the contrast observed should be that arising from features in the specimen and not due to incorrect adjustment of the microscope. The removal of a specimen (transmitted light) or the insertion of a perfectly flat reflecting mirror or speculum (reflected light) should result in a uniformly illuminated field under bright-field imaging conditions and a uniformly dark field under dark-ground imaging conditions.

### Sampling

The need to ensure that the specimen is a representative sample strictly relates rather to overall scientific methodology than to preparation procedures as such. However, the scientific or technological significance of the subsequent microscopical investigation

is ultimately determined by such considerations and indeed may be completely vitiated by unconsidered sampling or dissection procedures.

### Accessibility of Features

The conditions under which the features of interest in a sample are immediately accessible to the imaging system, i.e., such that no further specimen preparation is required (except for an appropriate mounting procedure), are generally limited to low-power techniques, which are normally appropriate to the initial stages of a scientific investigation. Under this category may come 'whole mounts' of biological organisms or parts of organisms, fracture and corrosion surfaces of metals, ceramics, and polymers, and strews of particulate materials (sands, dusts, etc.).

Otherwise the sample must be cut in one or more orientations and sectioned, ground, and polished as appropriate so that the features of interest can be revealed in the thin sections (transmitted light) or from their intersections with the prepared surfaces (reflected light).

### Contrast

Contrast in the image is provided in transmitted-light techniques by variations in the absorption, diffraction, and interference of transmitted light, or in reflected-light techniques by variations in the reflectance, diffraction, and interference of light reflected from the features of interest. Contrast in thin sections (transmitted and reflected light) is enhanced by staining techniques, i.e., the selective absorption or attachment of dyes or fluorochromes to specific structural elements in the material, and from surfaces in reflected light by etching techniques, i.e., the selective attack and staining of the features of interest and the boundaries between them.

In some materials such staining procedures are either unnecessary, difficult, or impossible to carry out, and contrast in transmitted light may be achieved by exploiting (small) refractive index differences between the features of interest, or in optically anisotropic materials by exploiting refractive index differences for light vibrating in different directions. The former is the basis of phase contrast and differential interference contrast techniques and the latter is the basis for polarized-light techniques (for birefringent materials). Such techniques are also applicable to reflected light: phase contrast and differential interference contrast techniques enhance surface topographical detail and polarized-light techniques reveal optical anisotropy between features of interest (for bireflectant materials).

### Stability

The requirement that the specimen should not deteriorate, and should remain representative of the original sample or (living) organism, must be assessed in relation to the appropriate time scale – no specimen is permanent! The problem is far more acute in the case of biological materials; in inorganic materials the surface degradation and corrosion that occurs (particularly in reactive metals) may be removed and the surface simply repaired.

Living organisms must be humanely killed in such a way that their tissues are as nearly as possible unchanged from those of the living state. Unless the material is to be examined immediately, the sample must then be fixed to maintain this state, and it is fixation that largely determines the distinction between ‘permanent’ and ‘temporary’ mounts.

### Optical Requirements

The optical performance of the imaging system of the light microscope is determined primarily by the objective lens, viz., its numerical aperture (NA) and the extent to which the lens is corrected for chromatic and spherical aberrations. The NA determines (1) the minimum resolved distance or resolving power of the system and (2) the extent or depth of field in the object that is in focus. Conventional light microscope objectives have NA values in the range 0.15–1.4, corresponding to a minimum resolved distance approximately in the range  $2\text{--}0.2\text{ }\mu\text{m}$  and a depth of field in the range  $20\text{--}0.4\text{ }\mu\text{m}$ . In addition to depth of field, the other constraint on specimen thickness is the confusion that may arise as a result of overlapping detail in the features of interest. For transmitted light, biological specimens are normally up to about  $10\text{ }\mu\text{m}$  in thickness; nonbiological materials (e.g., mineral thin sections) are generally examined rather thicker, and  $30\text{ }\mu\text{m}$  is a conventionally accepted standard. These thickness requirements are considerably relaxed in the case of ‘confocal’ light microscopy techniques, where the optical-sectioning characteristics enable out-of-focus blur to be suppressed and information about the third dimension to be incorporated in the final image. Specimens for reflected light should have surface topographic detail with height variations of the order of  $3\text{ }\mu\text{m}$  or less. The depth-of-field constraint is substantially less stringent in the case of stereomicroscopes, which normally operate at substantially lower effective NAs, in the range 0.01–0.1, and also at lower magnifications, providing a depth of field of several millimeters. The concomitant advantage of these instruments is that no specimen preparation at all may be required, the limitations to microscopic observation being set only

by the transmission of sufficient light in transmitted-light specimens and the depth of surface topography of reflected-light specimens. In the latter case, in particular, greater variations in surface topography than those given by the depth of field are readily accommodated by coarse-focusing adjustments.

## Preparation Techniques for Transmitted Light

### Techniques for Biological Specimens

Methods of collecting, culturing, handling, killing, and dissecting living organisms are outside the scope of this article and are extremely varied; they should follow normal practice for the organism under investigation. Biological specimens may be examined in many states, as combinations of the following: alive or dead, fresh or preserved/fixed, entire or in section, unstained or stained, hydrated or dehydrated, opaque or cleared.

Specimens sufficiently small to be examined entire may also be examined alive, contrast being provided by optical devices such as phase contrast or interference contrast microscopy, or occasionally by means of ‘vital dyes’ – nontoxic stains that have an affinity for certain components of cells. However, most organisms, their organs and tissues, and even their cells, are too large to provide high-resolution information with the conventional light microscope, and they must be killed and then (usually) dehydrated, embedded, sectioned, stained, and mounted before microscopical examination.

### Temporary mounts of entire, living specimens

Specimens originating as whole organisms or parts of living organisms require special treatment, either to maintain life during observation or to ensure that their death does not destroy the information of interest. Specimens examined by microscopy while still alive are generally small: whole organisms such as bacteria, Protista, and lower animals and plants, or discrete parts of organisms such as cells in culture, blood cells, pollen grains, etc. Depending upon the duration of observation and the nature of the specimen, attention must be paid to providing sufficient oxygen, maintaining concentrations of other substances (e.g., salts and ‘food’), removing carbon dioxide and other wastes, controlling temperature, providing adequate light, and excluding foreign organisms of predation or decay. Specimens of the types considered here will normally be mounted in the medium in which they occur naturally or are cultured, and techniques of preparation may be limited to mounting them on a slide, beneath a

coverslip, in a small drop of medium. If observation is to be prolonged, it may be necessary to retard evaporation by sealing the edges of the coverslip with petroleum jelly, nail varnish, rubber solution, or other suitable sealant. Conversely, the clarity of the image of organisms such as *Paramecium* increases considerably as the preparation becomes thinner and the organism more compressed on evaporation of fluid from beneath the coverslip. Some larger organisms can more easily be accommodated using a 'cavity slide', a slide with a shallow part-spherical depression. Cavity slides, or normal slides with a thin ring attached with an adhesive, can also be used for 'hanging drop' preparations. A small drop of medium containing the organism is placed on a coverslip; a ring of petroleum jelly is applied around the cavity or on the ring of the slide, the slide inverted over the fluid drop on the coverslip, and the whole then raised and turned over so that the drop hangs from the center of the coverslip. Such a preparation allows more prolonged observation before becoming anoxic than does a simple sealed preparation.

#### **Permanent mounts of dead specimens: fixation**

Organisms from which permanent mounts are to be made will necessarily be dead once mounted, so care must be taken that death occurs humanely and with as little alteration to the structure as possible. As soon as possible after death, and in some cases simultaneously with it, living tissues should be 'fixed', a process that 'kills' the cells, inactivates their enzymes (thus halting metabolism and preventing self-digestion), and precipitates and cross-links the molecules that are in simple or colloidal solution or suspension within the cells. All these actions stabilize the structure against damage during subsequent processing. Fixation must also act as a preservative against microbial decay, and may also improve a specimen's affinity for certain stains. Fixation is generally carried out by chemical treatment, though 'physical' fixation by heating or by rapid freezing may be used in certain circumstances.

Chemical fixative agents are many and varied, acting optimally on different constituents of living cells; combinations of several agents are thus frequently used together, a procedure that can also compensate for individual fixatives' shortcomings, such as a tendency to shrink or swell. Common fixative agents include formaldehyde (methanal) (typically a 4% w/v solution of the gas), ethanol (used undiluted), acetic (ethanoic) acid (5% aqueous), mercury(II) chloride (saturated aqueous), osmium tetroxide (1% aqueous), and glutaraldehyde (4% aqueous). Other substances such as picric acid, potassium dichromate, chromium trioxide, and many others have been used

for specialized purposes. Fixatives are generally used in aqueous solution, in saline, or in a buffer when maintenance of a specified pH is considered important. Traditional fixative mixtures still in current use include formaldehyde-saline (4% formaldehyde in 0.7% sodium chloride), and Bouin's solution (picric acid, formaldehyde, acetic acid). For high-quality preparations there is increasing use of fixative systems developed especially for electron microscopy (glutaraldehyde followed by osmium tetroxide). No single fixative mixture can serve all purposes; readers should consult specialist texts for information on choice and preparation of fixatives for specific specimens. Following fixation, it is generally necessary to rinse specimens free of fixative using water, buffer, or dilute ethanol.

**Dehydration and embedding** Whereas it is possible to make satisfactory sections of some plant material simply by skilled use of a razor, other specimens, particularly animal tissue, require more complex preparation. Animal cells lack the support provided by the cell wall of the plant, and thus must be provided artificially with adequate support before sectioning, conventionally by embedding. An embedding medium must be capable of infiltrating the tissue in the form of a liquid, and then solidifying, on cooling or by polymerization, to provide support from within the fine details of the specimen. The most commonly used embedding medium is paraffin wax, of a grade that melts at ~56°C. However, paraffin wax is not miscible with the aqueous fluid into which the fixed specimen has generally been transferred; the technique thus requires the specimen to be dehydrated, generally by passage through increasing concentrations of ethanol until absolute (100%) ethanol is reached. The time required for this will be minutes, hours, or even days, depending on the size of the tissue sample. Although ethanol is generally considered to be a suitable dehydrating agent, it nevertheless is not miscible with molten paraffin wax; replacement of the ethanol with a further, transitional, solvent that is miscible also with wax is thus required – common examples are xylene, toluene, or less-toxic, proprietary substitutes. After such a solvent has replaced the ethanol fully, the tissue is placed in molten wax for a period of ~1 h, during which time the wax infiltrates into the tissue. Finally, the tissue is transferred into fresh molten wax in a suitable container, and the wax is allowed to solidify. Alternatives to paraffin wax for specialized applications exist in the form of proprietary formulations, ester and polyester waxes, and also gelatin and celloidin (nitrocellulose), both of which require specialized sectioning techniques.

**Sectioning** As noted above, it may be possible to cut satisfactory sections freehand; most sections, however, are cut with the aid of a 'microtome' – a heavily built precision instrument designed to move a specimen block across the cutting edge of a sharp knife for sectioning, advancing the specimen toward the knife by a preset distance for each section. With good technique, sections may routinely be cut at 5  $\mu\text{m}$  thickness, and even thinner in some cases. Important factors in the sectioning process include the hardness of the wax block (dependent also on temperature), the cutting speed, the angle at which the knife is set with respect to the path of the block, and, most particularly, the characteristics of the knife (including angle of cutting edge, and its sharpness). Microtome knives are usually made of steel, sometimes in the form of small replaceable blades, and occasionally of tungsten carbide. Glass or diamond knives similar to those devised for electron microscopy may also be used for some specialized applications.

During cutting, successive sections attach together to form a 'ribbon' of sections, which is convenient to handle and mount. Sections are attached to clean microscope slides typically by floating them on a dilute solution of albumen, warmed on a hotplate to soften (but not melt) the wax, thereby to remove wrinkles in the sections, and allowed to dry in a warm place.

**Staining** Sections cut from wax-impregnated blocks must first be 'de-waxed' by immersion in a suitable solvent, traditionally xylene, now often replaced with a less-toxic proprietary substitute. This is generally followed by a succession of increasingly aqueous solutions of ethanol until the specimen is fully hydrated, since most stains are applied in aqueous solution. Once the support of the wax has been removed, the specimen should not be allowed to dry because of damage caused by surface tension.

Staining exploits chemical affinities, in general not well understood, between stains and substances present within the specimen. Some early histological stains were natural substances first used for dyeing textiles, selected for their affinities for cellulose (for dyeing cotton fabrics) or for proteins (the keratin of wool). Since the development of the first aniline dye in 1856, a vast array of stains has been available for experimentation by histologists. Nonetheless, one of the earliest stains, hematoxylin, a natural product extracted from 'logwood', remains one of the most important stains today, generally used to stain cell nuclei blue or black according to the method of application. The successive or combined use of several stains, including hematoxylin, each with its specific

affinity, provides the familiar 'trichrome' or more complex colorations of diverse tissue components.

The chemistry of some 'staining' techniques is better understood. For example, Schiff reagent gives a magenta color on reacting with aldehyde groups made available, for example, from polysaccharides by oxidation with periodic acid, or from DNA by hydrolysis with hydrochloric acid. Enzyme histochemistry relies on the capture of reactive products of enzyme action by appropriate components incorporated in an incubation medium, marking the location of enzyme activity by an inorganic precipitate or a dye. The most specific form of 'staining' in the widest sense of the term is seen in immunocytochemistry, where markers are attached specifically to target molecules within the specimen by means of the immune reaction. The technique requires antibodies specific to the substance under investigation, together with a means of localizing the antibody using a fluorescing substance or other marker.

Following staining, specimens must be dehydrated, cleared, and mounted, as outlined later.

#### **Preparation Technique for Transmitted-Light Microscopy of Nonbiological Materials: Fibers, Particulates, Petrological Thin Sections**

Nonbiological particulate materials (e.g., mineral grains) need no premounting preparation (see next section); biological particulate materials and fibers (e.g., pollen grains, wool fibers) normally require rinsing in alcohols, xylene, etc., to remove waxy surface films and pigmentation that may obscure the surface detail. In situations where it is necessary to maintain the distribution of the grains (e.g., soils, porous ceramics) the bulk specimen must be impregnated with a resin as described for reflected-light microscopy (see below) and a thin section is then prepared. Thin sections of soft materials (e.g., polymers) may be prepared by sectioning with a microtome in a manner analogous to that described above for biological specimens. Contrast between the features of interest (e.g., amorphous and crystalline regions) may be enhanced by staining and/or etching the section, but such techniques are generally rather difficult because of the chemically inert character of the material, and they are less structure-specific and much less developed than for biological material. Thin sections of hard materials (e.g., minerals, rock, ceramics, resin-impregnated ceramics) are prepared by a sequence of steps as follows: (1) cutting a thin plate  $\approx 1\text{ mm}$  thick, or 'chipping' a fragment from the bulk material; (2) mounting the plate on a glass slide using 'Lakeside' or an equivalent proprietary cement; (3) grinding, polishing, or lapping one side of the plate as described below for reflected-light

techniques; (4) mounting the plate polished-face-down on another slide and detaching the first; (5) grinding and polishing the (upper) as-cut surface to the required thickness; and (6) cementing a coverslip to the upper surface. The choice of abrasives and polishing materials is determined partly by the hardness of the material, but diamond abrasives are increasingly used because of their rapid-cutting qualities. It is normal practice in petrology to aim for a section thickness of 30  $\mu\text{m}$  (i.e., considerably greater than the norm for biological thin sections) because using polarized light (crossed polars) the minerals in such sections give polarization or interference colors that enable them to be readily recognized. Staining techniques for minerals and ceramics are not very widespread and are largely confined to those aggregates (e.g., sedimentary rocks) in which interference contrast is weak.

### Mounting

The final step in specimen preparation is to mount the prepared thin section, replica, fibers, or particulate strew, usually on a standard 25 mm  $\times$  76 mm (1 in.  $\times$  3 in.) glass slide, with a mounting material (mountant) (Canada balsam or its proprietary substitutes, glycerin, oils, aqueous liquids), and then to cover the preparation with a coverslip, a thin glass disk, or plate.

The thicknesses of the glass slide and coverslip and the refractive index of the mounting material and its suitability for the specimen are all factors that need to be considered. 'Dry' objectives are designed such that spherical aberrations are minimized when the specimen surface is covered by a glass slip of a given thickness and refractive index. This thickness is conventionally 0.17 mm and this assumes that the film of mounting medium between the specimen surface and coverslip is of negligible thickness. In order to fulfill this condition as closely as possible, it may be good practice to mount the specimen on the coverslip rather than the slide. Deviations from this condition are serious only for dry objectives of high NA (0.65–1.00), and such objectives may be provided with a 'correction collar'. This is adjusted so as to minimize spherical aberration for a range of coverslip-plus-mountant thicknesses, and may be graduated in arbitrary units or in millimeters; in the latter case it should be noted that the correct setting will be less than the coverslip thickness because of the necessity to take into account the mountant thickness. Spherical aberration corrections may also be made by altering the tube length of the microscope imaging system: shorter tube lengths are required when the coverslip-plus-mountant thickness is

greater than the conventional 0.17 mm and vice versa. However, this facility is not normally available in modern binocular instruments.

Glass slides are normally manufactured in a thickness range of  $\sim$ 0.75–1.5 mm. The thickness is an important factor for consideration principally in the case of dark-ground imaging using oil-immersion condensers of high NA that are designed to focus the hollow cone of light on the specimen at a given distance from their (top) working surface. Again, such condensers may be provided with a 'correction collar' so that this distance can be adjusted to suit the particular thickness of slide being used.

Immersion objectives are designed such that spherical aberrations are minimized when the appropriate medium (oil, water, or glycerin) lies between the front element of the objective lens and the coverslip. Immersion objectives may therefore be used equally for covered and uncovered (reflected-light) specimens.

For thin sections, and biological thin sections in particular, the mounting medium is chosen so as to be most appropriate to the specimen – i.e., whether it is a 'permanent' mount (in Canada balsam or its proprietary equivalents) or a 'temporary' mount (in glycerin, glycerin jelly, water-based materials). The distinction between 'permanent' and 'temporary' mounts is not rigid, and 'temporary' mounts may be sealed or ringed with varnishes and sealants of various kinds to make them 'semipermanent'. However, the important consideration is that the mountant should be inert, or act as a preservative against specimen degradation, within the observational time scale.

Transferring a hydrated biological specimen into an aqueous mountant may require little more than the appropriate manipulations, combined with warming the mountant in the case of glycerin jelly. However, nonaqueous mountants require in addition that specimens be dehydrated and transferred to a solvent miscible with the mountant. This is usually achieved using a series of aqueous solutions of ethanol of increasing concentrations leading to 'absolute (nominally 100%) ethanol', followed by xylene or a proprietary substitute for mounting in Canada balsam.

The refractive index of the mountant is a particularly important consideration for all preparations, because of its effects on the quality of the microscopical image, and on contrast in particular. Hydrated biological material frequently has a milky appearance, owing to scattering of light at the many interfaces between the aqueous components and the structures of higher refractive index (proteins, etc.).

Where the image is required to demonstrate optimally the distribution of stained material, the specimen should have approximately uniform refractive index throughout. This is readily achieved when the water is replaced by a suitable organic fluid (e.g., methyl salicylate, xylene, etc.) known as a 'clearing agent', and/or by infiltration and inclusion of the specimen in a resinous medium such as Canada balsam, whose refractive index is close to those of the tissue components.

In examining unstained and otherwise transparent biological objects, where contrast in the image must be achieved by phenomena other than the differential absorption of light, contrast will be increased according to the degree of mismatch between the refractive indices of specimen components and mountant, as discussed below for nonbiological objects.

In the case of fibers or particulate strews, the contrast of the fibers or particles is strongly determined by the refractive index differences between the mountant: nonabsorbing specimens of identical refractive index to the mountant having, of course, zero contrast. This provides an important means of identification of fibers and mineral grains: by immersing specimens in liquids of different refractive indices and by using the 'Becke line test' (which indicates whether the fibers or particles have a greater or lesser refractive index than the liquid), the refractive index (or refractive indices of birefringent materials) can be determined very accurately.

## Reflected-Light Preparation Techniques

### Initial Preparation and Mounting

In order to facilitate handling on the one hand, and to provide a sufficiently large representative specimen surface area on the other, the specimen dimensions should be in the range 5–15 mm in the prepared surface and 1–10 mm thick. Cutting such a specimen from a large piece of rock or a metal component, for example, must be carried out with considerable care; this apparently crude first step in specimen preparation must not be carried out by crude cutting methods that might overheat the specimen and give rise to cracking and changes in the structure. Considerable caution must be exercised, and samples in which it is suspected that inappropriate cutting methods have been used should be rejected. In many cases the orientation of the specimen surface (e.g., in relation to the host rock, or the metal component) is important and should be recorded.

Abrasive wet cutting, using metal or bakelite abrasive 'cut-off' wheels impregnated with alumina, boron nitride, silicon carbide, or diamond, is most appropriate and gives rise to minimum deformation of the cut surface. Wheels may be distinguished as 'hard' or 'soft' depending on their ability to retain or discard the abrasive particles. In general, the harder (more difficult to cut) materials require 'softer' wheels because these provide a continuous supply of new abrasive particles to the surface (but at the same time wear away more quickly).

There are two main mounting or embedding methods: 'hot compressive' mounting in bakelite or a similar thermosetting resin, which is carried out at elevated temperatures and pressures using proprietary equipment; and 'cold' mounting using mixes of resins and hardeners that set by polymerization and are poured around the specimen in a mould. Proprietary embedding materials (epoxies, acrylics, polyesters) are distinguished by their hardening rates, amounts of contraction (shrinkage), and final cured hardness. Epoxy embedding materials are also used, because of their low vapor pressure and viscosity, for the vacuum infiltration of porous materials, a procedure that is required (1) to stabilize the sample and (2) to prevent the ingress of the subsequent grinding and polishing compounds. In difficult cases, the impregnated epoxy may be mixed with a fluorescent dye to allow easy identification of the filled pores.

Clearly, 'hot' mounting methods cannot be used for temperature-sensitive materials, but otherwise they do in general provide a harder mount; this is particularly important in order to maintain a flat polished surface and good edge retention or definition. However, the continuing development, particularly of the polyester/acrylic resins, makes this distinction less evident.

### Grinding, Lapping, and Polishing

These procedures must be carried out with due regard to the precautions noted in the preceding section. Grinding is carried out by hand using paper-backed abrasive strips, or by using abrasive disks mounted on rotating wheels with successively finer grades of grit, normally silicon carbide for the coarser grades and  $\alpha$ - and  $\gamma$ -alumina and diamond for the finer grades. The silicon carbide grit particle sizes are distinguished by their sieve sizes or grades, and normally four such grades are sufficient, e.g., P240 ( $\sim 58 \mu\text{m}$  grit), P400 ( $\sim 35 \mu\text{m}$  grit), P600 ( $\sim 25 \mu\text{m}$  grit), and P1200 ( $\sim 15 \mu\text{m}$  grit). The abrasive papers must be thoroughly lubricated (usually with water) and the specimen (and fingers) thoroughly cleansed in order to avoid carryover of coarser grit to the finer

abrasive papers. Each stage may be regarded as complete when the underlying surface deformation has been completely obliterated. In practice, this means continuing the grinding for about twice the time required to remove the previous set of scratches.

The final lapping or polishing stages may be carried out with  $\alpha$ -alumina (particle sizes in the range 10–1  $\mu\text{m}$ ),  $\gamma$ -alumina (particle sizes  $\sim 0.3 \mu\text{m}$ ), or diamond (particle sizes in the range 6–1  $\mu\text{m}$ ). Normally only two stages are required. A choice has to be made with respect not only to the polishing compound but also to the cloth in which it is embedded, and to the lubricant. In general, soft cloths (those with a nap) and alumina compounds are appropriate to soft, friable, and easily damaged materials, but they do give rise to surface relief between hard and soft phases; this may be either an advantage or a disadvantage depending upon the end requirements. Hard cloths and diamond compounds are in general appropriate to hard materials. However, the distinction is by no means rigid and each specimen may have its own distinctive requirements.

In general, soft materials are more difficult to polish than hard materials. Insufficient lubricant, or cloths in which the abrasive is embedded too deeply to cut the material, may give rise to smearing in metals – the plastic deformation of the surface layers, which effectively obscures the underlying structure. In such cases the final step should be electropolishing, which involves no plastic deformation of the specimen surface.

Lapping is distinguished from grinding and polishing in that the abrasive particles are not stuck to a backing paper, or embedded within a cloth, but are free to move and roll freely across a relatively hard metal surface (e.g., cast iron) or become partially embedded in a soft metal (e.g., lead). Material removal rates during lapping in the former case are in general very low and the technique is generally confined to hard materials (ceramics, hard metals, etc.) in which surface finish is of prime importance. The use of soft laps is of particular importance in the grinding and polishing of minerals where the use of cloths results in unacceptable surface relief. Lapping is in general unsuitable for soft materials because of the problem of grit becoming embedded in the surface.

### Surface Treatments

For many materials (e.g., rocks, ceramics) no further treatment is required and the constituent phases may be sufficiently well revealed by their differences in color, bireflectance, and surface relief. For metals and alloys, etching treatments are required, but in any

event all materials should be examined in the as-polished condition to check for artifacts (e.g., localized smears or ‘comet-tails’) and to detect coarse inclusions and porosity that may be affected by etching processes.

Etching may be defined as the selective attack of grain and interphase boundaries and/or the selective attack of the phases themselves. In complex microstructures no single etchant may be effective and different etchants may be required in order to reveal different elements of the microstructure. Etchants usually consist of aqueous or alcoholic solutions and mixtures of salts, acids, and alkalis; the more corrosion-resistant metals and alloys (e.g., stainless steels) naturally require more aggressive solutions. The etching process consists simply of dipping or swabbing the specimen in the etchant, or of electrolysis, with the specimen acting as the anode of the electrolytic cell. The range of etchants and etching conditions practically equals the range of materials and microstructures to be examined. Like staining, it is very much a matter of experience and experimental skill – incorrect choice of etchants, etching time, etc., simply leads to an overall attack on the specimen surface, revealing no detail at all. Ion bombardment is another method for etching.

The etching process may be partially combined with the final stage of polishing; the etchant is added to the polishing compound and contributes to the overall material removal rate as well as reducing any tendency to smearing. However, a postpolishing etching stage is normally required.

Finally, contrast between phases may be revealed or enhanced by developing a thin (interference) film on the as-polished or polished-and-etched specimen surface. The technique is based on multiple-beam interference between the light reflected from the air-film and film-substrate surfaces, and the colors that occur are determined by such factors as film thickness, refractive index, and absorption coefficient. The film may be developed by anodizing (in which case it is restricted to oxides of the metallic specimen) or it may be deposited by vacuum evaporation or reactive-ion sputtering (in which case there is no restriction either to the deposited film or to the specimen). Anodizing is carried out using a range of oxidizing reagents and is a process analogous to electroetching except that the cell conditions are adjusted to develop an oxide film on the specimen (anode) surface. In practice, the two processes may be carried out sequentially.

Contrast enhancement by deposition of a metal oxide, sulfide, selenide, etc., film is a relatively new technique (interference film microscopy) and also lends itself to quantitative interpretation.

## Introduction

Because of the current tendency to develop integrated multipurpose electron microscope systems based on transmission electron microscope (TEM)/scanning transmission electron microscope (STEM) or scanning electron microscope (SEM) instruments equipped with multiple detector systems, and using different diffraction methods and observation modes, conventional TEM, STEM, and SEMs have evolved into a true analytical electron microscopy (AEM) tool. The aim of AEM is to determine the crystallinity, morphology, phase, and elemental compositions of a material using the signals generated in the course of the focused electron-beam interaction with the specimen. In this article, history and development stages of EM are considered; the basic theory of the EM is introduced followed by a discussion on TEM imaging and aberration correction. Finally, some brief considerations in standard TEM and SEM instruments and in the limitations of EM are presented.

## Microscopy: The History of a Challenge

The immediate purpose of microscopy is to enhance our unaided eyesight in examining objects whose details are not otherwise clearly resolvable. It is an old

problem that people have tried to resolve since ancient times. In 1897, Ernst Abbé presented his famous wave theory of the microscope, which predicted that the ultimate limit of the light microscope was set by the finite wavelength of light rather than by the accuracy of current optical manufacturing techniques. As the microscopes, made to Abbé's design, at Carl Zeiss Jena had aberration-free objectives, it meant that further improvement in resolving power was possible. The resolution, i.e., the distance  $d$  between two small adjacent particles that are just distinguishable from each other, is given from optical theory by

$$d = \frac{0.61\lambda}{n \sin \alpha} \quad [1]$$

where  $\lambda$  is the wavelength of the light,  $\alpha$  is the semi-angle of the cone of rays entering the objective lens, and  $n$  is the refractive index of the region between the specimen and the near surface of the objective. In an optical microscope, the semiangle can, in principle, be close to  $\pi/2$  radians and hence  $\sin \alpha$  is close to unity. Since the wavelength of visible light is  $\sim 550$  nm, the theoretical resolution of the microscope is  $\sim 340$  nm in air ( $n = 1$ ). This can be pushed down to 227 nm by oil immersion ( $n = 1.5$ ). In nonvisible ultraviolet illumination, which precludes the use of glass lenses, it might be possible, at a wavelength of 220 nm, to achieve a resolution of  $\sim 100$  nm with quartz lenses. This is still inadequate for the needs of researchers in the fields of materials science and life sciences. The atomic spacing of gold, for example, is 0.2 nm. There was therefore no hope, using the light microscope, of seeing fine detail in

## Introduction

Because of the current tendency to develop integrated multipurpose electron microscope systems based on transmission electron microscope (TEM)/scanning transmission electron microscope (STEM) or scanning electron microscope (SEM) instruments equipped with multiple detector systems, and using different diffraction methods and observation modes, conventional TEM, STEM, and SEMs have evolved into a true analytical electron microscopy (AEM) tool. The aim of AEM is to determine the crystallinity, morphology, phase, and elemental compositions of a material using the signals generated in the course of the focused electron-beam interaction with the specimen. In this article, history and development stages of EM are considered; the basic theory of the EM is introduced followed by a discussion on TEM imaging and aberration correction. Finally, some brief considerations in standard TEM and SEM instruments and in the limitations of EM are presented.

## Microscopy: The History of a Challenge

The immediate purpose of microscopy is to enhance our unaided eyesight in examining objects whose details are not otherwise clearly resolvable. It is an old

problem that people have tried to resolve since ancient times. In 1897, Ernst Abbé presented his famous wave theory of the microscope, which predicted that the ultimate limit of the light microscope was set by the finite wavelength of light rather than by the accuracy of current optical manufacturing techniques. As the microscopes, made to Abbé's design, at Carl Zeiss Jena had aberration-free objectives, it meant that further improvement in resolving power was possible. The resolution, i.e., the distance  $d$  between two small adjacent particles that are just distinguishable from each other, is given from optical theory by

$$d = \frac{0.61\lambda}{n \sin \alpha} \quad [1]$$

where  $\lambda$  is the wavelength of the light,  $\alpha$  is the semi-angle of the cone of rays entering the objective lens, and  $n$  is the refractive index of the region between the specimen and the near surface of the objective. In an optical microscope, the semiangle can, in principle, be close to  $\pi/2$  radians and hence  $\sin \alpha$  is close to unity. Since the wavelength of visible light is  $\sim 550$  nm, the theoretical resolution of the microscope is  $\sim 340$  nm in air ( $n = 1$ ). This can be pushed down to 227 nm by oil immersion ( $n = 1.5$ ). In nonvisible ultraviolet illumination, which precludes the use of glass lenses, it might be possible, at a wavelength of 220 nm, to achieve a resolution of  $\sim 100$  nm with quartz lenses. This is still inadequate for the needs of researchers in the fields of materials science and life sciences. The atomic spacing of gold, for example, is 0.2 nm. There was therefore no hope, using the light microscope, of seeing fine detail in

bacteria, the structure of viruses, or the molecular and atomic structure of the cell or of metals.

Abbé himself, along with many others, did not believe that it would be possible to harness alternative radiation, such as X-rays or electrons, to the task of forming high-resolution images. Nevertheless, his wave theory of the light microscope applies remarkably well to the modern analytical electron microscope, in which the wavelength itself is not a limitation. The (dualistic) wavelength of an electron depends on its momentum, decreasing rapidly as the momentum increases. In many charged-particle devices, the electron velocity approaches that of light, so that relativistic theory is needed to estimate the wavelength. It may be readily calculated from the expression

$$\lambda = \frac{1.23}{V_r^{1/2}} \quad [2]$$

where  $\lambda$  is the wavelength (in nanometers) and  $V_r$  is the relativistically corrected acceleration voltage (in volts). Table 1 shows the electron wavelength, in nanometers, for the range of accelerating voltages  $V$  for electron microscopes now in commercial production. In the range of accelerating voltages from thousand to a million volts, the wavelength itself is therefore not a limiting factor in resolving any known structure.

This background information became available to scientists in 1924. Electron microscopes evolved in a similar empirical way to that of the light microscope, but over a brief 30-year period, compared with the many centuries needed to develop the light microscope.

The development of essential components of electron microscopes – such as electron sources, high-acceleration voltage generators, fluorescent screens, photographic plates, and beam scanning devices – had begun for use in cathode-ray oscillographs around the end of the nineteenth century. It was also known that a magnetic solenoid or ‘converging coil’ could focus a diverging beam of cathode rays (electrons) into a small spot. In 1924, Hans Busch in Jena showed theoretically that there is a close analogy between this action and that of a glass lens on light. However, it was Ernst Ruska and his Ph.D.

supervisor, Max Knoll, at the Technische Hochschule in Berlin, who, inspired by Busch’s theory, actually designed and built the first two-stage transmission electron microscope. In April 1931, they took the first TEM micrographs, at a magnification of some  $13\times$ , quite low by light microscope standards, but the design principle was established. In 1933, Ernst Ruska, working alone, designed and built a transmission electron microscope with a resolution better than that of the light microscope.

In 1935, Knoll devised and constructed the scanning electron microscope at Telefunken Berlin. In this microscope, a focused beam (‘electron probe’) is scanned in TV raster fashion across a solid specimen. In an SEM, the TEM column is in effect inverted to produce a demagnified image of ‘electron probe’ from the source. Electrons scattered by the specimen are detected and modulate the intensity of the beam of a cathode-ray oscilloscope scanned in synchronism with the electron probe. In Knoll’s SEM, the magnification, which is simply the ratio of the length of the scan on the screen to that on the specimen, was hardly more than unity, but the principle of imaging the surface of solid specimens was established. Its practical realization was beyond the technology of the time, but 50 or so years later it became a strong competitor of the TEM.

In 1938, again in Berlin, Manfred von Ardenne introduced a hybrid microscope. His newly devised scanning transmission electron microscope accepted a thin TEM specimen, which was scanned by a fine electron probe as in the SEM. The electrons leaving the specimen, having interacted with the atomic structure of the specimen, were collected and allowed to modulate a recorder placed immediately underneath the specimen and scanned in synchronism with the primary scanning beam, as in the SEM. As with the SEM, the principle in the STEM was demonstrated but the electronic technology at the time, and the limitations of the thermionic gun, were inadequate for commercial production. Ardenne’s motivation for the STEM was that since there were no lenses between specimen and detector, the chromatic aberration produced by the TEM objective lens would be absent. This is true, but inelastic scattering in a thick specimen can itself lead to delocalizing effects and hence loss of resolution.

The main disadvantage of scanning methods is that information is acquired serially, pixel by pixel, whereas in TEM all pixels are imaged simultaneously, leading to a much shorter exposure time. High-brightness field-emission guns (FEGs) now eliminate this difficulty. Although FEGs were being developed at the time by W.O. Mueller elsewhere in Berlin, they operated in all-glass high-vacuum systems that were

**Table 1** Electron wavelength ( $\lambda$ ) at various accelerating voltages in commercial electron microscopes

Voltage (kV)	$\lambda$ (nm)
1	0.04
100	0.004
1000	0.001

very inconvenient. Continuously pumped high-vacuum systems did not become generally available for STEMs and SEMs until the 1960s, when they were introduced into the STEM by A.V. Crewe in Chicago.

TEMs itself took off suddenly in 1939, with the installation of the Siemens Uebermikroskop (Super-microscope), the first serially produced transmission electron microscope, with a remarkable resolution of some 7 nm at IG-Farben in Germany. Thus, in a period of 8–9 years, the principal electron microscopes had been conceived and built in experimental form, and a commercially produced transmission electron microscope had begun to be used routinely in manufacturing industry. Today's electron microscopes offer the possibility of producing images with atomic resolution over a wide range of specimens. This is in itself a tremendous achievement. However, it should be noted that this is necessary but not sufficient condition for deducing the atomic structure of an unknown specimen. Although it is possible to calculate the image of a given structure, it is in general not possible to reverse this procedure. In practice, therefore, electron microscopists must learn how to interpret their images, using the many simulation techniques and other sources of information now available to them.

## Theory of Electron Microscopy

Fortunately, many ideas needed in electron microscopy can be taken over from optical microscopy theory. This applies both to wave optics and geometrical optics. Wave optics is particularly helpful in clarifying operation at high resolution, where phase-contrast effects predominate. Geometrical optics is important for understanding the action of the lenses in the column.

### The Electron Optical Column

A standard TEM is shown in Figure 1. Its general construction resembles that of the light microscope. The electron source at the top of the column emits electrons, which are accelerated, in this case, to 200 kV. The effective source size is small, some 25  $\mu\text{m}$  in diameter for a thermionic source, down to 2.5 nm for a field emitter. This source is further demagnified by the multiple lens system forming the illuminating beam. An illuminated area ranging from 3 mm, the size of a specimen grid, down to 0.5 nm, can be produced at the specimen plane located at the center of the air gap of the objective lens (OL) as shown in Figure 1. The objective lens lies at the heart of the instrument, as it alone determines the resolution that can be achieved. The objective is provided

**Figure 1** Cross-section of the Topcon EM-002B 200 kV column. CL, condenser lens; ML, minilens; OL, objective lens, with specimen in the center of the air gap; IL, intermediate lens; PL, projector lens. (The Topcon Corporation, Japan.)

with a set of apertures that enable the operator to alter image contrast and attainable resolution. The subsequent projector lenses project the image produced by the objective, or its associated diffraction pattern in the back focal plane, onto the fluorescent

screen, photographic plate, charge-coupled device (CCD) camera, or image intensifier recording system. The operator's task is thus to select the field of view, focus the image, correct any astigmatism, and record the image.

### Resolution

The wave optics of the light microscope is generally applicable. Because of the smaller working aperture of the electron microscope, for a TEM, the limiting resolution  $d$  as given by eqn [1] reduces to

$$d = 0.6\lambda/\alpha \quad [3]$$

where  $\lambda$  is the wavelength and  $\alpha$  is the semiangle of the TEM objective or the corresponding angle in the probe-forming lens of an SEM or a TEM. For example, for a resolution of 1 nm in an aberration-free TEM operating at 100 kV,  $\alpha = 2.2 \times 10^{-3}$  rad. Such an angle is minute compared with that of a light microscope; this is a consequence of the remarkably small wavelength of the electron. Fortunately, electron sources are many orders brighter than the light sources used on optical microscopes, so that the intensity of the illumination in such a small solid angle is adequate to provide a satisfactory image at the  $100\,000\times$  or so magnification needed to resolve this detail on the fluorescent screen. It is quite feasible with modern image recording systems to work, in ordinary room lighting, at magnifications of several million times. In fact, such magnifications are often essential in the critical alignment and adjustment of a TEM and an STEM.

The resolution  $d$  in eqn [3] is analogous to the 'half-width' of the Airy disk that is observed in astronomical telescopes when viewing point objects such as stars. The Airy disk arises from the diffraction of rays from the finite aperture of the optical system; its diameter can be reduced by increasing the aperture of the lens. In an electron microscope, this cannot be done because of the severe spherical aberration of electron lenses (correctors for spherical aberration are being developed now, so this situation could change in the near future). The effect of spherical aberration is to broaden the Airy disk and reduce its height, thereby reducing image contrast and worsening the resolution. A simple way of visualizing this broadening is to note that the disk diameter of spherical aberration in the Gaussian image plane is given by

$$d = 2C_s\alpha^3 \quad [4]$$

where  $C_s$  is known as the coefficient of spherical aberration. In an electron microscope,  $C_s$  is typically of the order of 1 mm or so for the objective lens. A point

object will thus appear as a disk whose diameter increases rapidly with  $\alpha$ . The diffraction error decreases, but more slowly, with increase in  $\alpha$ .

There is an optimum angle, as indicated by wave optics. For example, the effect of spherical aberration of the objective is to distort the wave leaving the specimen from the spherical shape produced by a perfect lens. This unwanted extra pathlength PD inserted into the wave is given by

$$PD = \frac{C_s\alpha^4}{4} \quad [5]$$

Lord Rayleigh considered this problem and concluded that in any optical system an unwanted pathlength of  $\lambda/4$  or less can be tolerated, as having an extremely small effect on the size of the Airy disk.

Hence, if  $C_s\alpha^4/4 = \lambda/4$  is set, then

$$\alpha_{\text{opt}} = \left(\frac{\lambda}{C_s}\right)^{1/4} \quad [6]$$

is obtained for the optimum angle  $\alpha_{\text{opt}}$ . Substituting in eqn [3] gives the optimum resolution  $d$  as

$$d = 0.6(C_s\lambda^3)^{1/4} \quad [7]$$

In an STEM, with a Rutherford angular back-scatter detector, the imaging may be incoherent, i.e., largely free from diffraction effects. Under such conditions, the above constant is reduced to 0.43, a notable gain in resolution compared with a conventional TEM. Equation [7] is especially important for evaluating the capabilities of different TEM instruments. Notice that the resolution depends more strongly on  $\lambda$  than  $C_s$ , and this encourages the use of high-accelerating voltages (small  $\lambda$ ).

It is clear from eqns [6] and [7] that the objective aperture must be large enough to allow the finest detail required to pass through. The smallest aperture that satisfies this condition should be chosen. Otherwise, chromatic aberration may unnecessarily obscure the image. Chromatic aberration arises mainly from the fact that electrons passing through the specimen suffer energy losses. Plasmon losses occur that are associated with inelastically scattered electrons that suffered collective electron excitations giving rise to broad peaks in the range 0–50 eV. The emission of X-rays by various elements in the specimen also leads to corresponding discrete energy losses in the imaging beam. Moreover, in all electron lenses, the refractive power varies with the energy of the electrons traversing the lens. From a geometrical point of view, the diameter of the disk of confusion  $d_c$  in the Gaussian image plane is given by

$$d_c = 2C_c\alpha\frac{dV}{V} \quad [8]$$

where  $C_s$  is the coefficient of chromatic aberration and  $\alpha$  is the semiangle of the cone of rays between specimen and focusing lens;  $V$  is the accelerating voltage and  $dV$  is the energy spread in the electrons. If the accelerating voltage of the lens excitation changes, further chromatic aberration will appear in the image; this may be avoided by well-designed electronic supplies having a stability of a few parts in a million for subnanometer resolution. In the limit, variations in the energy of the electron source, 0.1 eV for an FEG, can also destroy the contrast of fine detail in the image.

### The TEM Image

The TEM image is not simple to understand at high magnification, but the light microscope can provide some useful insights into the reasons for this. In the light microscope, there is no spherical or chromatic aberration. This means that the magnified image faithfully represents, in amplitude and phase, the wave leaving the specimen. The photographic plate or the CCD camera does not respond to phase and so this information is unfortunately lost. Such images are referred to as 'amplitude' contrast images. Zernike found that by placing, in the objective lens, a quarter-wave plate with a central hole to transmit the unscattered rays, an image containing phase information (phase-contrast image) could be produced.

Unfortunately, all attempts to create such a plate for the TEM have failed, causing a serious problem, since the chief contrast mechanism in the TEM at high resolution is phase contrast caused by elastic scattering at individual atoms. In the absence of a phase plate, some other means must be found to transform this into an amplitude contrast that can be recorded on the fluorescent screen or CCD camera. Spherical aberration itself (see eqn [5]) can insert a phase change into the wave leaving the specimen. It can also be arranged to provide a rough-and-ready phase plate. The spherical aberration coefficient of the lens is fixed, but by slightly decreasing the excitation current of the objective lens and hence its refractive power, to the so-called 'Scherzer defocus', a Zernike plate of sorts can be created that produces a phase-contrast image over a limited but useful range of spatial frequencies.

A typical phase-contrast transfer function is shown in Figure 2. This representation of TEM performance is analogous to the audio frequency response of a hi-fi amplifier. The units of spatial frequency here are reciprocal nanometers ( $\text{nm}^{-1}$ ), high values of spatial frequency corresponding to fine detail. The curve shows that the response of a conventional TEM in high-resolution mode is complicated and initially

**Figure 2** Typical phase-contrast transfer function of a high-resolution 200 kV TEM for  $\text{LaB}_6$  and field-emission guns. (Reprinted with permission from Coene W, Janssen G, Op de Beeck M, and Van Dyck D (1992) Phase retrieval through focus variation for ultra-resolution in field-emission transmission electron microscopy. *Physical Review Letters* 69: 3743–3746. © American Physical Society.) (Courtesy of Dr. W. Coene, Philips Research Laboratory, Eindhoven.)

mystifying. Practically no large area (low spatial frequency) phase-contrast information is transmitted. There is then a flat portion of the transfer function transmitting detail over the range 1–0.25 nm after which the contrast falls to zero. This point is known as the 'interpretable resolution limit', in this case  $\sim 0.25 \text{ nm}$  ( $4 \text{ nm}^{-1}$ ). Beyond this point the curve oscillates rapidly in phase, making it impossible to interpret the image visually. Nevertheless, this part of the transfer function contains encoded information about the finer details in the specimen. Under coherent illumination, spherical aberration, unlike chromatic aberration, does not destroy this information and it can, therefore, in principle, be recovered.

The envelope of the transfer function tails off exponentially with spatial frequency as shown in Figure 2. This is caused partly by energy changes in the electron beam, in the limit from the energy spread at the gun cathode. Figure 2 shows the transfer function for a lanthanum hexaboride and for an FEG, which has a lower energy spread. The other factor is the finite spatial coherence, or angular spread, in the illuminating beam. Here, the FEG scores again because of its much higher beam brightness (current density per solid angle). As soon as the transfer falls to the level of random noise, information is irretrievably lost. This important point is known as the 'information limit', in this case  $\sim 0.125 \text{ nm}$  for an FEG.

An FEG is essential for reaching the information limit by means of image decoding methods, and similarly the mechanical and electronic stability have to be compatible with this limit. From the point of view

of an operator working beyond the interpretable limit, what is more serious about spherical aberration is that, although fine detail remains reasonably sharp, this aberration can encode image detail. Thus, amplitude contrast is wrongly converted to phase contrast and vice versa, making the task of image interpretation very difficult at the atomic level and necessitating extensive image-simulation checks.

Fortunately, it is now possible to record phase- and amplitude-contrast information independently by electron beam holography, invented in 1948 by D. Gabor, but only made possible at the atomic level by developments in digital computing in the early 1990s. In a form of this method, known as 'off-axis holography', which has been brought to success by H. Lichte and his colleagues at the University of Tübingen, the TEM specimen is illuminated by a coherent beam of electrons from an FEG. Part of the beam is prevented from passing through the specimen, but acts as a reference beam for determining the phase of the wave. The two beams are merged lower down in the column by a Fresnel electron biprism located in the plane of the selected area aperture above the first projector. An off-axis interferogram (hologram) is formed that contains the complete information, in amplitude and phase, about the wave leaving the specimen, including the distortion of the wavefront by electron-specimen interaction, spherical aberration, defocusing, etc. The hologram is digitized and fed into a computer, which corrects the spherical aberration and astigmatism and produces images in amplitude and in phase contrast, just as is possible in the light microscope, but at atomic resolution. Such images form an accurate starting point for the determination of the object structure. Currently, modern instruments can be easily adapted for off-axis holography.

In 1992, an alternative technique for the correction of spherical aberration was developed by W. Coene and his colleagues at Philips Research Laboratory, Eindhoven, and at the University of Antwerp (RUCA). This is more computer intensive but does not require a biprism or any modification of the TEM column. It makes use of the fact that with coherent illumination the individual transfer functions of a focal series of images overlap and therefore contain, in coded form, the complete information about the wave leaving the specimen, not just to interpretable resolution limit but right down to the information limit of the microscope. Using the terminology of radio communication, which gives a good insight into the methods of holography, the basic carrier wave has to be separated from the two sidebands carrying the information about the specimen. In 'in-line' holography, as originally proposed

by Gabor, all three are superposed, so that the sidebands can interfere with each other, causing serious artifacts in the reconstruction. By advances in programming techniques, it is now possible to isolate the offending nonlinear terms that arise in the analysis of the images. By inserting the known spherical aberration coefficient into the program and adopting a least-squares fit approach to a set of some six or seven images in the series, it has proved possible to achieve aberration-free atomic resolution in a commercially produced 300 kV TEM. This is a great step forward since this procedure can be carried out on any high-performance TEM equipped with a CCD camera.

Using phase-contrast imaging, correction of the spherical aberration constant, or electron holography, electron microscope resolution has been increased over the years in order to improve visual interpretation of the images. The state-of-the-art spatial (point) resolution in a TEM has been limited to  $\sim 0.15$  nm, although this value is now decreasing due to recent improvements in microscope design and computer processing. More common dedicated high-resolution TEMs have a spatial resolution of 0.17 nm, while general-purpose microscopes have spatial resolutions of slightly more than 0.2 nm.

Since the work of Crewe in the early 1970s and pioneered by Pennycook in 1988, the Z-contrast imaging technique represents a different approach to atomic resolution electron microscopy. It allows 'incoherent' imaging of materials and provides directly interpretable images maps of the specimen at the atomic scale, in which higher atomic numbers (Z) show brighter. The Z-contrast image is obtained by scanning an electron probe of atomic dimensions across the specimen and collecting incoherent electrons elastically scattered at high angles, using a high-angle annular dark-field detector. The scattered intensity is understood as a sum of independent scattering from individual atoms, so the incoherent images of the Z-contrast method are interpreted more directly in terms of atom types and positions, since each summation, or integration, has the effect of suppressing the interference contrast that tends to produce image artifacts in phase-contrast images. Effects of contamination and beam damage must be minimized. In 1993, following the investigations of Browning and Pennycook, the Oak Ridge National Laboratory (TN, USA) took delivery of the first 300 kV Z-contrast STEM, providing a resolution of 0.13 nm.

### Correction of Chromatic Aberration

It should be noted that the direct correction of spherical and chromatic aberrations in electron optical

lenses has been actively pursued since about 1936 by the insertion of quadrupoles, sextupoles, and octupoles into the column. In recent years, good progress has been made, leading the way to the commercial development of aberration-corrected TEMs. In 1998, Haider and co-workers, following the work of Rose, introduced the first successful aberration corrector for the imaging geometry used in a conventional TEM. Current studies on spherical aberration corrector open the door to a three-dimensional, sub-angstrom imaging of atomic arrangements.

What firstly succeeded is electron spectroscopic imaging in the TEM, by means of focusing energy spectrometers. The basic idea here is to design an energy spectrometer that also has the properties of an axially symmetric (round) lens and so can take its place in the TEM column as an extra projector lens between the final and intermediate projectors. Such a device has several advantages and was available in certain Zeiss TEMs for sometime.

The electron diffraction pattern that appears in the back focal plane of the objective lens is also a powerful analytical tool. Unfortunately, this pattern is often overlaid by the diffuse background of inelastically scattered electrons, which do not contribute to the diffraction pattern but are defocused by the chromatic aberration of the objective lens. This causes loss of contrast in the pattern and also in a high-resolution image. These effects can be removed by allowing only elastically scattered electrons to reach the final screen. Figure 3 shows the results of this removal; it demonstrates that, with this designed filter using only magnetic focusing and correcting elements, the quality of the pattern is better than in unfiltered TEMs, even those working at more favorable, higher voltages.

**Figure 3** Diffraction pattern of a decagonal quasicrystal in CoNiAl alloy. Comparison between selected-area diffraction patterns of the same specimen, a CoNiAl quasicrystal, in a conventional (unfiltered) 200 kV TEM (left) and in a 125 kV EM912 Omega TEM with magnetic energy filter (right). Filtering enhances the visibility of low-intensity spots and fine structure close to the direct beam. Specimen and image: Max Planck Institute for Metal Research, Stuttgart, Germany. (Courtesy of Carl Zeiss, Germany.)

With a selective energy imaging filter, positive advantage can be taken, for analytical purposes, of the elemental information in electrons that have suffered a defined energy loss through ionization followed by X-ray emission (element mapping). Previously it was necessary to use the STEM mode for such work with a conventional energy spectrometer as

**Figure 4** Schematic arrangement of the electron probe micro-analysis detector and backscattered detector (BSD) in the twin-lens objective Philips CM30 TEM/STEM and the STEM and EELS (energy loss) detectors below the final projector lens. The postspecimen beam deflection system is used to deflect the electron beam to either detector. (Courtesy of Philips Ltd., Eindhoven.)

shown schematically in Figure 4. With an electron probe of  $\sim 2$  nm, one can obtain STEM images and electron energy-loss spectra (EELS), thereby obtaining an elemental map of the specimen. This can now be done in parallel operation with an imaging filter in the TEM. The first practical imaging energy filter was devised by Castaing and Henry in 1962 and eventually fitted in a Zeiss EM902A TEM between the first and second projector lenses as shown in Figure 5. The magnetic prism bends and focuses the incoming electrons into an electrostatic mirror that reflects the electron beam back onto the optical axis of the TEM. Because of the high degree of symmetry, aberrations are minimized and the system acts as a one-to-one magnification round lens for both images and diffraction patterns.

In the early 1990s, a magnetic filter (the Omega energy filter), capable of operating at higher accelerating voltages, was realized by Rose and Krahl in Germany and commercially available in the Zeiss (now LEO) EM912 Omega TEM. An important operational point here is that the imaging of all electrons is carried out at the same accelerating voltage as far as the column is concerned. For example, when

imaging electrons that have lost 200 eV, the computer increases the accelerating voltage by 200 eV. This brings these electrons to the nominal accelerating voltage of the microscope and avoids alignment difficulties and ensures high precision of measurement. Because of some delocalization of inelastically scattered electrons, the image resolution is  $\sim 2$  nm, similar to that for standard 200 kV TEMs equipped for X-ray probe analysis. Element mapping is therefore a very useful and rapid analytical feature in a TEM. In 1994, Uhlemann and Rose proposed a new imaging magnetic energy filter (the Mandoline energy filter, also developed by LEO), which even increased the energy resolution by one order of magnitude compared with then commercially available filter microscopes.

## Instrumentation and Results

Nowadays, there is a tendency to develop integrated multipurpose EM systems based on TEM/STEM or SEM instruments equipped with multiple detector systems, and using different electron and X-ray diffraction methods and observation modes. As a result, conventional TEM, STEM, and SEM instruments have evolved into a true AEM tool, which uses most of the signals produced during interaction between electron beam and sample.

### TEM and STEM

After 70 years of evolution, today's electron microscopes follow broadly similar electron optical designs, differing mainly in their orientation to either materials science or biological applications and in the special facilities that are required in different disciplines. It is not possible here to give a comprehensive survey but only to select some representative designs.

Referring again to the Topcon ABT EM-002B TEM shown in Figure 1, this design is interesting since it occupies an intermediate position between standard 100 kV TEM designs and 300 kV TEMs using techniques to produce aberration-free images. The EM-002B column is completely computer controlled allowing it to switch rapidly between TEM operation with a resolution of 0.18 nm, as shown in Figure 6, to electron probe X-ray microanalysis in the specimen stage with a probe size of 2.5 nm. The ringed area in Figure 6, in which the lattice planes in the specimen are clearly resolved, indicates the sort of microarea that becomes instantly available for selected area diffraction and X-ray microanalysis. The minimum probe size is 0.5 nm, a considerable design achievement in a TEM. In order to manage

**Figure 5** Schematic arrangement of the operating modes of the Castaing-Henry magnetic sector, electron mirror, imaging spectrometer as incorporated in the Zeiss EM902A TEM, showing path of monoenergetic electrons  $E$  through the system. (Courtesy of Carl Zeiss, Germany.)

this effectively, five condenser lenses, including the prefield of the objective, are needed, with close computer control of excitations to enable the probe to be focused without upsetting the focus of the objective. The correct setting of the objective lens for STEM and microdiffraction operation is aided by two minilenses placed on each side of the lens gap. An interesting feature is that the polepieces of the objective lenses may be exchanged, in a matter of 15 min, for example, in order to have a larger angle of tilt (with a slight loss of resolution), without dismantling other parts of the column.

### Scanning Electron Microscope

These instruments rely heavily on electron-optical developments from a TEM. The chief advantage of an SEM is that virtually no specimen preparation is necessary and large objects may be examined. For example, Figure 7 shows the escapement of a wristwatch, taken at a magnification of  $6 \times$ . The depth of focus is extremely high compared with that of a light microscope and it is even possible to take video pictures of the mechanism in operation. Figure 8 shows the cross-section of the column of the Topcon SM-700/700 SEM, an instrument with, unusually, two mechanical stages. The top stage is for high-resolution (2 nm) work, with the specimen up to 8 mm in

**Figure 7** SEM image of the escapement of a wristwatch, taken in a CamScan Series 4 SEM, illustrating the remarkable depth of focus compared with the light microscope. (Courtesy of Obducat CamScan Ltd.)

diameter; the lower stage is for a more modest resolution (5 nm) but with specimens up to 100 mm in diameter. The accelerating voltage may vary from 40 to 2 kV. At 2 kV the resolution is a useful 8 nm. A  $\text{LaB}_6$  cathode is needed to achieve these results. This design illustrates what trade-offs have to be made in the examination of a wide range of specimens. For even higher resolution, commercial SEMs are available with field-emission cathodes. The gain in resolution is typically by a factor of 2 or more, but greater care must be taken to ensure a pressure less than  $10^{-7}$  Pa in the gun region.

One may conclude this section by noting that TEM, STEM, and SEM are fast approaching the limits set by basic physics. State-of-the-art instruments rely increasingly on computers to carry out the complex adjustments that are needed for high performance, and also to record and produce the images and spectra that can be acquired.

### Limitations of Electron Beams in Microscopy

In the early days of electron microscopy the instruments were fairly daunting to use. Most of those early problems have now been brought under control by the manufacturers. In addition, computer control of alignment, autofocus, and automatic control of the intensity of illumination as a function of magnification are now common features of current microscopes. CCD cameras and other computer-based methods now produce high-quality images. For digital data acquisition, CCD cameras offer excellent sensitivity and linear response over a wide range of intensity. They provide image output in near real time, and

**Figure 8** Cross-section of the column of the Topcon SM-700/700 Dual-Stage SEM, showing the high-resolution objective in the top stage and the versatile conical objective lens in the second stage. (The Topcon Corporation, Japan.)

CCD cameras are often integrated into postcolumn energy filters, although these cameras do not provide the same resolution as the photographic film. The much superior sensitivity of CCD cameras at low electron exposures is a clear advantage for beam-sensitive materials, however. Many STEMs designed for research in surface science operate routinely at ultra-high vacuum, essential in critical work in this area.

With the great range of TEMs, STEMs, and SEMs now available, the range of acceptable specimens is extremely wide. Low-voltage ( $< 1$  kV) SEMs can give useful information on beam-sensitive materials such as biological specimens or very large scale integrated circuits. At the other end of the range the atomic perfection of a heterojunction in a semiconductor device can be demonstrated by a 300 kV TEM.

Specimen preparation methods have also improved enormously in the last decades and a wealth of documentation is now available. Specimen preparation methods such as ion beam thinning enable one to prepare thin transverse sections of an interface that can be imaged at atomic resolution in a 300 kV TEM. With so many techniques available, it is not

possible to say in advance what is or is not feasible in specimen preparation. A limitation in practice may well be the cost of preparing 'difficult' material to the high standard that is often demanded.

The ultimate limitation of electron beams in microscopy is, of course, the radiation damage they can inflict on the specimen. This is fundamental and unavoidable, although the damage extent depends on the electron dose needed to collect a correct signal, which in its turn is also influenced by the instrument performance. The atomic resolution that can be achieved in the electron microscope arises from the strong interaction between electrons and matter right down to the atomic level. This can cause rapid degradation in many crystal structures, but can often be alleviated by cooling the specimen to liquid-nitrogen or liquid-helium temperatures and carefully organizing the imaging system to minimize the number of electrons needed to take an exposure. The other side of the coin, of course, is that radiation damage in materials can often be studied more effectively and cheaply in a million-volt TEM than in a nuclear reactor!

## Introduction

Although it is common practice to separate materials science techniques from the life sciences, there is enough common ground in specimen preparation to combine them in one article.

However, the preparation for transmission electron microscopy (TEM), requiring thin samples (less than 100 nm) to allow the electron beam to penetrate the sample, will be discussed separately from scanning electron microscopy (SEM) methods since these normally require bulk preparation where sample stability and conductivity are the main criteria.

## Thin Sample Preparation Techniques

### Support Films

The most commonly used support films are either ultrathin carbon films or Formvar films stabilized with carbon. Essentially the carbon is vaporized in a vacuum chamber by passing a high current through two carbon rods. The carbon is deposited on to a

suitable substrate, normally freshly cleaved mica or a glass microscope slide. Thickness can be estimated by the color of the carbon deposit on a white surface; light brown represents ~20 nm. The film on the coated mica is then floated off on to a water surface (Figure 1), collected on to 3 mm grids, normally made from copper, and finally dried at room temperature.

This type of film is a suitable substrate for collection of particulate material as a 'dry-dusted' dispersion; as its name suggests, dry powder is sprinkled on the coated grid and the excess is removed, leaving relatively few particles adhering to the carbon film, usually sufficient for a standard for X-ray microanalysis. When a better dispersion is required, ultrasonic agitation is employed in an ultrasonic bath; if there is difficulty dispersing the sample, an ultrasonic

**Figure 1** Method for preparing carbon-coated grids.

probe immersed in the suspension is more likely to be successful. The choice of solution will depend on the material to be dispersed but could range from water to a solvent such as petroleum ether. The choice will depend on solubility and density.

Although carbon films are easily prepared, they need to be made hydrophilic by exposing them to a glow discharge or ultraviolet (UV) irradiation to ensure an even distribution of a water-based suspension such as a virus concentrate. The final preparation of the virus concentrate would have to be stained with a negative stain such as phosphotungstic acid; the stain surrounds the particles and these then appear bright against a dark background. Alternatively, Formvar films stabilized with carbon can be used. One of the methods for making these films is to prepare a 0.5% (w/v) solution of Formvar in chloroform, spread this evenly over a clean microscope slide, and cut round the edges of the film. The film is then floated off on to a distilled-water surface, collected on to copper grids, and finally coated with ~10 nm of carbon.

A modification to the above film, made by adding glycerin to a 0.25% Formvar–chloroform solution and dispersing this by ultrasonic agitation, will produce a network of holes. After collection of the film on to grids, methanol is used to remove the glycerin. The grids are then carbon coated and immersed in chloroform to remove the Formvar, thus producing an ideal support for material where the carbon structure is limiting the performance. Only regions across holes are examined. The concentration of glycerin will determine the size of hole. If the film is being used only as a test specimen, ~2% is adequate; when it is used purely as a supporting net, 10% will be more suitable.

### Replicas and Extraction Replicas

Although replication of surfaces is not required very frequently, there are occasions when it is not possible to view the entire surface in an SEM owing to size or perhaps when a timed sequence of events is involved. More frequently it is necessary to extract precipitates, inclusions, etc., from a matrix and to view these in a TEM without interference from the matrix.

There are two possible ways to prepare these replicas: one will not damage the sample and is ideal when the inclusions, etc., are easily removed; the other is a destructive technique that requires the matrix to be dissolved, leaving only particles of interest on the carbon film.

In the first case, cellulose acetate sheet is moistened with acetone and 'rolled' on to the surface, where it is left for ~30 min and then stripped off the surface,

attached to a glass slide and coated with ~20 nm of carbon. The cellulose acetate is then removed in acetone by placing grids on to a metal gauze with sufficient acetone to allow capillary action to wet the surface of the gauze. (This process is left in a covered environment for several hours.) Although this is a slow method of removing the acetate, it does prevent the carbon film breaking and the grid is ready for examination as an extraction replica. If the replica is for surface examination only, it will be necessary to shadow at an angle with some suitable metal (Au/Pd, Pt, or Pt/C) to improve image contrast.

For the second method, the surface is lightly etched to reveal the particulate to be removed, then coated with 20–40 nm of carbon. The carbon is scored into ~3 mm squares and sufficient matrix is removed to allow the film to float off on to the etching solution. The carbon film is then transferred to a clean water bath where it can be collected on to the grids.

### Thin Samples for Materials Science Applications

There is a need to make a thin sample that represents the bulk without introducing defects into the thin sample. The sample is ideally less than 100 nm thick, of uniform thickness, and both mechanically stable and electrically conductive under the electron beam. Methods to be considered are electropolishing, ion beam thinning, and ultramicrotomy.

The choice of method depends on the sample; if it is conducting, e.g., a metal foil, then electropolishing will normally be the answer since this is the fastest method available. However, if the sample is non-conducting, or is multiphase with one phase thinning faster than the others, then ion beam thinning will be preferable. If the sample is a powder or a thin wire, then the ultramicrotome may provide a solution depending on the hardness of sample.

Before a description of the final thinning stage it is necessary to outline initial preparation. (1) Cut a slice as thin as possible, realistically 200–500  $\mu\text{m}$ . (2) This is mechanically polished to 50–100  $\mu\text{m}$ . (3) Punch/drill out a 3 mm disk. (4) Preferentially polish the center of the disk by 'dimpling' the sample (optional).

**Electropolishing** Essentially this is the reverse method of electroplating. Here the sample is held in an electrolyte (5% perchloric in methanol is a good starting point), with the sample as the anode and a stainless-steel cathode. When a suitable voltage is applied, material is removed from the sample, usually to perforation, allowing a thin area to be examined around the hole. In the method's simplest

**Figure 2** (A) Simple electropolishing system with the specimen supported by forceps as the anode. (B) A schematic diagram of the electropolishing jet thinner (cathode not shown).

form a thin foil may be used as shown in **Figure 2A**, with an insulating layer painted around the contacts; this is usually 'Lacomite' the trade name for a solvent-based lacquer colored red to render it more visible. A DC power unit supplies a voltage from 0 to 120 V with typical values of 30 V and 0.1 A; perforation of the foil is decided by visual inspection. A more commonly used thinning system is one that is designed to produce a jet of electrolyte on either side and at the center of the disk, with a beam of light used to detect perforation (**Figure 2B**). Temperature, voltage, and flow rate are all variables that allow the sample to be polished rather than etched, with typical polishing times of a few minutes. The initial polishing action is to remove any surface asperities to provide a smoother starting point that facilitates a faster process and a better final result.

A comprehensive list of sample preparation techniques and electrolytes for different materials is given in the microscopy handbook by Goodhew (see Further Reading section).

**Ion beam thinning** The idea of this technique is to bombard the sample with a beam of argon ions to remove surface atoms, thus thinning the specimen. The ion guns are designed to produce a fine beam of ions and/or neutral atoms. In its simplest form, an

**Figure 3** Schematic of an ion beam thinner showing the specimen mounted at 45° with respect to the ion guns.

ion gun is a hollow anode and cathode, with the applied voltage and resulting discharge ionizing the argon gas. The variable parameters that determine the thinning rate are current and voltage, the higher the current and voltage, the faster material is removed, but there is an upper limit as the sample will be damaged by the higher-energy argon ions. Specimen tilt will contribute to the size of thin area ultimately produced; the lower the glancing angle of the beam to the specimen, the larger the area (the geometry of the system will limit this to  $\sim 12^\circ$ ) but the longer the thinning time. It is therefore common practice to start with a higher angle and to reduce it part way through the sequence. A gun either side of the specimen allows the option of thinning from one or both sides (**Figure 3**). During the entire thinning process the sample is continually rotated. It is often necessary to reduce the specimen temperature to avoid heating effects and therefore a liquid-nitrogen stage is normally provided as an optional extra. Thinning times will vary for different materials; typical thinning times are 30 min for a 4  $\mu\text{m}$  copper foil and several days for a 100  $\mu\text{m}$  ceramic material. Even foils of the same thickness but different elemental composition have vastly different thinning rates. For example, the maximum sputtering yield expressed in atoms/ion (argon) will range from 2 for aluminum through 4 for elements such as iron and tungsten to 20 for zinc. Because of these differences, when thinning compound semiconductor material 'reactive' iodine gas is often used, since this limits the preferential thinning observed with argon ions by combining chemical and ion etching.

**Ultramicrotomy** This is normally associated with biological samples but can be used with great success on materials science samples. **Figure 4** outlines the principle of the technique: a knife, which has to be

**Figure 4** Simplified diagram of an ultramicrotome demonstrating the movements of the specimen block.

diamond for most inorganic samples, is designed to move up and down against a sample advancing at rates of nanometers per step. Thin sections are produced and are normally collected on a water surface. The critical parameters are the knife angle, the shape of the specimen block, and the cutting speeds. The specimen block will have been produced by embedding the sample in a suitable resin that matches the hardness of the sample. For materials science use, a hydrophilic acrylic resin such as 'LR White', which offers grades from soft to hard, is ideal since it does not require mixing with hardener and cures at 60°C. Its main disadvantage is that air must be excluded during the curing process. This has been used successfully for embedding fine powders, thin wires, and multilayers of different material. A recent publication by Jacobs has shown that cyanoacrylate ester ('superglue') added before embedding can reduce the problem of the resin becoming detached from the material.

Samples of aluminum foil were prepared by each of the above techniques and, as expected, they produced essentially the same thinned specimen with the exception that the grain boundaries were less obvious in the sectioned sample (probably owing to the lack of any preferential thinning). The ion beam-thinned sample was more irregular since the initial surface was not perfectly flat. Since the sample is readily thinned by electropolishing, this would be the normal method selected.

An extension to normal ultramicrotomy is cryoultramicrotomy, in which, as the name suggests, the temperature of both the specimen and the knife is reduced. The temperature depends on the glass transition temperature of the material. A sample such as polymer film on aluminum substrate can be prepared only in this way, and **Figure 5** shows the aluminum foil, an oxide layer, and the polymer coating.

The techniques described so far have all produced plan-view samples, but occasionally it is of great

**Figure 5** Transmission electron micrograph of a polymer-coated aluminum foil: A = aluminum, O = oxide, P = polymer film.

**Figure 6** The initial stages in the preparation of a cross-section specimen: (A) bonded layers before polishing; (B) after the first polishing stage with a layer bonded to either end; (C) showing the position from where the 3 mm disk will be taken.

interest to examine layers such as GaAs and GaInAs deposited on a matrix. For this, it is necessary to produce thin 'cross-section' samples. Preparation of a cross-section is a tedious but necessary procedure as described by Brawman. A slight modification involves bonding several layers together (**Figure 6A**), and polishing top and bottom until flat. Two layers, one at either end, are bonded at 90° to make the structure more rigid as shown in **Figure 6B**. After mounting on a glass microscope slide, with cover slips either side for reference, the entire sample is polished to the level of the cover slips. A 3 mm disk is removed using a hollow drill (**Figure 6C**), dimpled and ion beam-thinned. With luck and careful alignment of the ion guns, the sample will perforate at the interface. With use of a variable speed of rotation during the thinning process (fast when the

argon beam ‘sees’ the join), there is less chance of the specimen breaking at the vital point.

### Focused Ion Beam Sample Preparation

Two tools, which have become widely used during the 1990s for preparing specimens for material analysis, are focused ion beam (FIB) and FIB/SEM systems. As its name suggests, an FIB system uses a beam of focused ions (usually gallium) to sputter (cut) away material to prepare the specimens. Similarly to SEM, the FIB beam can be scanned over the sample and the generated secondary ions or secondary electrons (SE) used for imaging. The ions are field extracted from a liquid metal ion source and are accelerated (30–50 kV), collimated, and focused by a series of electrostatic lenses and apertures. A beam typically varies from 1 pA to 20 nA and the corresponding spot sizes range from 10 to 500 nm. An FIB/SEM has both an electron beam and an ion beam column, usually inclined at 52° to one another. **Figure 7** shows an FEI dual-beam FIB/SEM system.

FIB and FIB/SEM systems are routinely used to prepare TEM lamellae (both cross-section and plan views) and SEM specimens, which have been used for secondary ion mass spectrometry, electron backscatter diffraction, and Auger analysis. These systems offer numerous advantages relative to the other techniques described in the previous sections. The main advantage is that the specimens can be prepared to within 50 nm of a feature of interest (FOI). Other advantages are: (1) the lamella can be prepared with near parallel sidewalls enabling quantitative chemical analysis to be performed over the lamella; (2) the ion beam is perpendicular to the surface of the sample so that less preferential milling occurs than with ion beam thinning; and (3) the sample preparation time can be as short as 2 h.

**Figure 7** A FEI dual-beam FIB/SEM system.

Currently, three techniques – the ‘lift-out’ technique, the trench technique, and the wedge technique – are used to prepare TEM lamellae. Typically, the prepared TEM lamellae are 10–15 μm wide, 8–10 μm deep, and 50–100 nm thick. In all three techniques, the first step involves depositing a 1 μm thick and 1 μm wide metal strap (usually Pt or W) using ion- or electron-beam-assisted deposition (a suitable precursor gas is bled into the chamber) over the FOI to protect it from being milled and to planarize the sample’s surface.

In the lift-out technique, a lamella is free from the sample and is lifted on to a carbon-coated TEM support grid using a needle and micromanipulator. Two cuts are milled on either side of the metal strap and then the material between the cuts is thinned to 300 nm by scanning the ion beam in lines (a similar procedure to slicing a loaf of bread). The sample is next tilted to 45° and the base and sidewall of the lamella are cut. After retilting to 0° the lamella is further FIB milled to electron transparency (50–100 nm) and its remaining sidewall is cut to free it from the sample. It is then lifted from the cuts by using either a glass or metal needle and a micromanipulator. This step is generally performed *ex situ* of the FIB chamber using an optical microscope but it can also be done in an SEM or FIB/SEM using secondary electron imaging. **Figure 8A** shows an SEM image of a free lamella that is being lifted out by a tungsten needle. The needle is repeatedly swept through the FIB cuts until the lamella attaches to it through electrostatic forces. A carbon-coated TEM grid then replaces the sample and the needle is swept across the carbon surface until the lamella attaches to the carbon membrane. **Figure 8B** shows a lamella that has just been placed on to the carbon support membrane by the needle. The success yield of this step is ~70%; the lamella may be ‘lost’ by falling off the needle during the lift-out step or when placing it on to the grid.

The trench technique has success yield of ~99% and involves preparing a slice of material from the sample (usually 5–100 μm wide) by dicing or polishing and fixing this on to a U-shaped TEM grid (**Figure 9A**). Trenches are then FIB milled from the edges of the slice to either side of the FOI to make the TEM lamella and a pathway for the electron beam in the TEM (**Figure 9B**). A drawback of this technique is that the trenches limit the angles to tilt in the TEM.

The wedge technique is a hybrid of the trench and the lift-out techniques, combining their relative advantages; it was developed using an FIB system and involves *in situ* micromanipulation. A wedged-shaped piece of material (typically 5–10 μm wide) is cut free from the sample by making four

**Figure 8** SE images of a lamella (A) being lift-out from the FIB cuts using a metal needle and (B) being placed on to a carbon support membrane.

**Figure 9** (A) Mounting of a slice on to a U-shaped TEM grid and (B) SE image of a finished trench cross-section showing the trenches and the TEM lamella.

interconnecting cuts. The end of a needle is then 'welded'/fixed, using *in situ* metal deposition, to the wedge (Figure 10A). The wedge is next lifted and positioned against the sidewalls of a TEM grid where it is fixed using metal deposition. At this stage the needle is cut from the wedge and moved away and the TEM lamella is FIB milled into the wedge. Figure 10B shows a wedge fixed to a TEM grid into which the lamella has been milled.

Variations of these three techniques are used to make plan-view lamellae. In the methods based on the trench and the lift-out techniques, the samples are cleaved or polished and placed end-on to the FIB. In the methods based on the wedge technique, the wedge is rotated by 90° before being fixed to the side of the TEM grid.

Site-specific SEM cross-sections are prepared in exactly the same way as TEM cross-section lamellae for the lift-out technique except the cuts are only made on one side of the Pt strap. This is shown schematically in Figure 11.

### Focused Ion Beam Artifacts

Unfortunately, the incident energy of the ion beam can create vacancies and interstitials at the sidewalls of the lamella, which, if of sufficient density, can result in dislocations or formation of an amorphous layer. For example, in silicon lamellae the amorphous layer at the sidewalls is 20 nm thick. However, there have been many reports of successful ways to reduce the depth of the damage at the sidewalls and to further reduce the thickness of the lamella. These include milling the sidewalls of the lamella using a 5–10 kV ion beam in the FIB chamber, using gas assisted etching, ion beam milling outside of the FIB chamber, and tilting the samples by large angles (5° and above) during the FIB milling to electron transparency.

However, despite these limitations, FIB and FIB/SEM systems have become very important tools for making site-specific specimens and preparing specimens from samples composed of materials with different sputter rates.

**Figure 10** SE images (A) of a needle attached to a wedge shaped piece of sample and (B) of a wedge that has been fixed to a TEM grid into which the TEM lamella has been milled.

**Figure 11** Schematic of a SEM cross-section.

### Biological Sample Preparation

Again the requirement is to produce a specimen representing the original live tissue but, since there have to be many chemical processes, doubt can be raised regarding the validity of the final result. Hence, controls are always run at the same time and under identical conditions, with changes from control being the most significant observation. If a new technique is employed, then comparison with previous established techniques is essential.

Which technique is used depends, to some extent, on what is required from the observation. For example, during processing by conventional methods, virtually all elements such as sodium and potassium are removed. Therefore, X-ray analysis for these elements would be useless; however, the morphology is totally acceptable. Other elements may survive the processing and the only consideration for X-ray analysis is interference of overlapping peaks due to the fixation and stain.

**Fixation** Speed is important since the tissue will deteriorate within minutes. The decision on immersion fixation, against per-fusion fixation, will depend on what else has to happen to the tissue – if biochemical analysis is required then obviously perfusion fixation is not an option. There is no doubt, however, that perfusion fixation can be an advantage, as shown in the comparison micrographs of liver in **Figure 12**. Here the sinusoid and associated cells are more readily seen in the perfusion-fixed sample.

Glutaraldehyde solution is used for the first stage, normally at ~4% in buffer, and the pieces of tissue are immersed for 4 h. The buffer is designed for correct osmolarity, ionic constitution, and pH of the living tissue. The tissue is then transferred to buffer and undergoes several washes before being postfixed with osmium tetroxide 1.2% for 2 h (these times depend on the size of the tissue sample). After several washes in buffer, the next stage is dehydration. Another common variation is to block-stain with uranyl acetate.

**Dehydration and embedding** It is essential to remove all water from the tissue. This is achieved by a graded series of water–alcohol mixes, starting with 50:50 water–alcohol to finally 100% absolute alcohol. The tissue is immersed in each wash for ~10 min, and the sample containers should be capped at all stages to avoid absorption of water from the atmosphere. After the final wash in absolute alcohol, depending on the next stage a secondary wash in a different solvent is required. If epoxy resin is to be used for embedding, then a change to propylene oxide is achieved by 50:50 dilutions and finally 100% propylene oxide.

Finally, the sample is embedded by immersing first in a 50:50 dilution of resin in propylene oxide, then

**Figure 12** Transmission electron micrographs of liver sections: (A) by immersion fixation; (B) by perfusion fixation.

to at least two changes of 100% resin, and curing at the appropriate temperature.

**Sectioning** The ultramicrotome described earlier is used to obtain sections that are  $\sim 40$  nm thick. Since biological tissue is easier to cut than inorganic samples, a glass knife may be used rather than diamond. However, the speed and performance advantages of diamond far outweigh the cost. The ribbon of section so produced can be picked up on a grid, which usually does not need to be coated with a support film. A thin (5 nm) carbon film evaporated on to the final section can, however, decrease charging in the TEM.

**Staining** An unstained section, even postfixed with osmium tetroxide, will result in a very low-contrast image. Poststaining with uranyl acetate and lead citrate, when specificity is not important, is the normal method for increasing the contrast for morphological examination. This is a positive staining technique in which the stain reacts chemically with some of the cell components to produce regions of high atomic number composition. The result is additional scattering of the electron beam and hence an increase in the image contrast.

If X-ray analysis is required, the addition of these heavy elements can interfere with the elements to be examined and it thus may be necessary to exclude one or both of the stains. It can be also an advantage to increase the thickness of the section so as to increase the volume of material to be analyzed.

Apart from the minor changes to the above procedure to compensate for different types of tissue, a significant change to fixation will normally be necessary to accommodate immunohistochemical techniques, since antigens may be destroyed by the fixation. This may be a change to 0.5% glutaraldehyde in paraformaldehyde and no postfixation in osmium, to removal of any conventional fixation chemical. In this case cryofixation is the solution, but subsequent sectioning is somewhat more involved.

**Cryotechniques** For TEM it is necessary to freeze the sample rapidly to avoid ice crystal damage, usually by 'slam freezing'. With this technique 10–20  $\mu$ m of the tissue surface will be suitable for morphological as well as chemical and biochemical analysis. The sample may be cut using a cryoultramicrotome and viewed either in its hydrated form or freeze-dried. This sample will be virtually chemically correct and certainly suitable for immunocytochemical analysis. The method suffers, however, from one disadvantage in that there is almost no contrast to determine the structure of the tissue in the TEM.

Freeze-substitution is perhaps of more use; here the sample is frozen rapidly and then held in an organic solvent such as ethanol for several days at  $-80^{\circ}\text{C}$  to remove the ice. After embedding in a resin and polymerization with a UV source, sections are cut and, if necessary, stained. The resultant section will be ideal for any examination and most types of analysis.

**Freeze–fracture** This technique is equally useful to TEM or SEM examination. Here the sample is rapidly frozen as previously described, and if a replica is required the sample is evacuated in a specialized coating unit. Once at a suitable vacuum, the sample is fractured, coated with carbon and shadowed with a heavy metal; after removal from the vacuum unit, the sample is thawed and the coating is removed to produce a carbon replica. The material will fracture at the weak points of the tissue, such as along membranes, revealing internal structure in this high-resolution image that can be examined in the TEM. It is also possible to freeze-etch the sample after fracture, but before replication, to reveal specific detail. As with any technique, considerable thought must be given to possible sources of artifacts.

For details of all the specimen preparation methods and related techniques see the Glauret series.

If SEM examination is required, there is no need to replicate the surface since it can be examined directly in the SEM, again with or without freeze-etching. (It will probably be necessary to coat the surface before examination.)

## Bulk Specimen Preparation

Almost any material can be observed within the SEM. Scientists routinely look at materials as diverse as contact lenses and engine parts, through to the fat particles in milk and crystals in diesel oil. The common factor between all types of specimens is the need to make them ready for viewing in the microscope.

The first question that a scientist should ask when considering a piece of material for SEM observation is ‘does it need to be prepared?’ Will the act of preparing the specimen damage the detail required to be imaged, or even remove the detail completely? If a specimen is being examined for the surface residue, almost any preparation may remove the information required. However, if the surface required resides beneath a contaminated surface, there is a possibility that this film will require removal. If the task is to determine elemental distribution by backscattered electrons, it is ideal to present a polished surface to the electron beam, as surface roughness will interfere with the signal produced. Similarly, a polished surface is also desired for most accurate X-ray analysis.

### Adhesives

The specimen will need to be mounted upon a metal disk, which is known as a stub. The disk may be the top surface of a short rod or the upper surface of a pin-shaped unit. Adhesion may be provided by a layer on the under surface of the specimen or, if the

specimen is transparent to the electron beam, by using the adhesive to tag the corners of the specimen to the stub. Proprietary clamping units may be used, but only if the specimen is sufficiently robust to tolerate the pressure exerted by the clamps.

**Proprietary adhesives** Many of the adhesives available for fixing metal to metal or porous material to metal will be suitable for use in the scanning electron microscope. The problems however are twofold: first, the adhesive may take a long time to give off its solvent; second, the adhesive may be nonconducting, insulating the specimen from earth. A nonconducting adhesive could create a surface charge that would destroy the image quality. The former may be overcome with patience, the latter either by careful control of the microscope parameters or by coating the specimen with carbon or a metal.

**Special adhesives** Silver Dag<sup>TM</sup> is the most commonly used adhesive in the scanning electron microscope. It not only dries quickly but also provides a conducting interface between the specimen and the mount. Carbon suspension, a carbon-based adhesive, shares with Silver Dag<sup>TM</sup> the properties of fairly rapid drying and conductivity. The main advantage of carbon suspensions is that with care they may be used with almost any specimen, no matter how fine. Carbon is a poor electron emitter and therefore does not ‘hide’ the specimen. Consideration must be given to any possible effects of the adhesive solvent on the sample.

For fine particles, a stub is cleaned by rubbing it on a clean piece of paper. A thin layer of carbon suspension is then wiped across the surface of the stub with one smooth movement. When the carbon dries and is almost totally matt, the specimen is deposited on to the surface. The excess is shaken off, leaving the material adhering to the stub (**Figure 13**). If one practices with sugar, the technique has failed if the sugar adheres but has turned black.

**Adhesive tapes and tabs** A very wide range of adhesive tapes is available in various forms: single-sided, double-sided, copper, aluminum, and now carbon. The main advantage with a tape or a tab is that very fine specimens may be mounted quickly. The main disadvantage, apart from outgassing of the tape in the microscope creating high levels of contamination, is that sticking the specimen on to a tape means a commitment to coating, unless the tape is in the form of carbon tape ‘tabs’, which seem to be an almost perfect mounting medium.

Another point worth noting is that particles on tapes may often become mechanically unstable in the

**Figure 13** (A) A typical specimen stub. (B) The initial stage of carbon suspension application. (C) The carbon covering the entire stub. (D) The particulate material adhering to the coated stub.

electron beam as they sit on small strands of material. Glass coverslips make an ideal clear background on which to sit a specimen that is in suspension. The coverslip is mounted on to a stub and is coated with a metal for  $\sim 2$  min before placing on to it a drop of suspension. The slip is then earthed by running a trace of silver dag from the top surface down to the specimen stub itself. If the sample is very irregular (or even very regular such as a large sphere), problems may arise in attaching the sample to the stub and in creating a conducting path, since very often there is only point contact with specimen 'overhang'. A somewhat larger quantity of adhesive will be required to ensure contact with the largest diameter of the specimen, and additional care is needed in forming the conducting path.

It is often useful to modify a standard stub to accommodate irregular samples, such as by drilling a small hole in the center or possibly adding a spike to impale the sample. Such modifications can increase the mechanical stability.

### Coating Techniques

Why is it necessary to coat specimens before inserting them into the SEM? In the first case, the specimen is coated because nonconducting specimens build up a surface charge, thus deflecting the major imaging signal, the SEs. Therefore, the image viewed may be distorted in both signal level and image form. In the second case, coating provides a surface layer that produces a higher SE yield than the normal specimen material.

The use of an SEM to observe as many specimens as possible in an uncoated form should be

**Figure 14** A schematic diagram demonstrating the principle of sputter coating.

encouraged, because only uncoated specimens are guaranteed to display the true surface structure. If a coating is required to make the surface more easy to handle in the microscope (less charge and distortion), the following sputter coating technique should be adopted.

In a low-vacuum environment (5–1 Pa; 0.05–0.01 mbar), a gold (gold–palladium or platinum) target is bombarded with argon ions. Erosion of the target takes place and the electrode arrangement causes the metal to deposit on all surfaces within the chamber, including the specimen (Figure 14). With a modern 'low-voltage' coater, metal may be deposited at up to  $50 \text{ nm min}^{-1}$ , which enables a sufficient coating to be put down in  $\sim 30$  s.

Sputtered metals are deposited in the form of islands, not a continuous coating. Although the coating will be relatively random, a coating unit should be tuned to obtain the optimum grain size, coating penetration, and coating thickness for the task in hand. Multiple coatings should be avoided as they produce small gold 'hills', adding features to the specimen surface. For use at the very low SEM magnifications, a coating that appears gold in color is desirable. This very thick coating will provide a high signal while protecting the specimen from the high beam currents used at these levels. When the specimen is to be investigated over a range of magnifications, it is important not to coat the surface with any more gold than will give a gray tint to the specimen ( $< 10 \text{ nm}$ ). This thickness is more than sufficient to obtain satisfactory results without forming an undesirable 'carpet' over the fine detail. For many electron microscopists, coating the specimen is a

standard procedure. It should be pointed out that specimen damage during sputter coating is one of the most common artifacts in scanning electron micrographs. There are very few specimens that, if correctly prepared, may not be viewed without coating, provided the SEM is operated at low accelerating voltages and with appropriate care.

If the sample contains water, this will have to be removed before examination by SEM. There are basically three methods: air drying, freeze drying, and critical-point drying (CPD). The one used will depend on the sample. Air drying is the quickest but the sample will distort and shrink unless it is protected by a rigid 'shell'. If the only interest is X-ray analysis, this may not be a problem. Freeze drying, i.e., rapid freezing and then removal of the ice, usually in a specialized vacuum chamber, is ideal for samples such as wood, but critical point drying is most commonly used. The object of this technique is to remove the water initially by solvent extraction (as in thin section), then after the 100% alcohol step to change to acetone, and finally in the CPD apparatus to substitute the acetone for liquid carbon dioxide. Conversion from the liquid phase to the gaseous phase is achieved at elevated temperature and pressure. The critical point is the change from liquid to gas 'without change of volume'. In reality, the volume change is minimized but it does occur, and this must be considered when finally viewing the sample.

It would be preferred that the specimen could be viewed without preparation, and for this reason cryostages and environmental chambers exist. As mentioned previously, it is possible to freeze-fracture tissue to reveal the internal structure, but it is

possible also to fracture the critical-point-dried sample, which will be very brittle. The resultant image is limited only by the fixation method.

Only the most commonly used techniques have been described, and it is inevitable that each specialized requirement will modify or create a new method.

## Introduction

Scanning electron microscopy (SEM) is one of the most versatile and widely used of the surface analytical techniques as it allows both the morphology and composition of various materials in modern science to be studied. It is considered a relatively rapid,

inexpensive, and basically nondestructive approach to surface analysis. It covers a number of areas of application like biology, geology, metallurgy, semiconductor research, and catalysis. The first scanning electron microscopes-used to examine thick specimens was described by Zworykin and co-workers in 1942, but the first commercial scanning electron microscopes, based on the work of Oatley and co-workers at Cambridge University, became available only in 1965. Since then, many advances have been made owing to improvements in lens design, high-brightness electron sources, new detectors, and electronic signal processing. Nowadays there are many different types of scanning electron microscope

standard procedure. It should be pointed out that specimen damage during sputter coating is one of the most common artifacts in scanning electron micrographs. There are very few specimens that, if correctly prepared, may not be viewed without coating, provided the SEM is operated at low accelerating voltages and with appropriate care.

If the sample contains water, this will have to be removed before examination by SEM. There are basically three methods: air drying, freeze drying, and critical-point drying (CPD). The one used will depend on the sample. Air drying is the quickest but the sample will distort and shrink unless it is protected by a rigid 'shell'. If the only interest is X-ray analysis, this may not be a problem. Freeze drying, i.e., rapid freezing and then removal of the ice, usually in a specialized vacuum chamber, is ideal for samples such as wood, but critical point drying is most commonly used. The object of this technique is to remove the water initially by solvent extraction (as in thin section), then after the 100% alcohol step to change to acetone, and finally in the CPD apparatus to substitute the acetone for liquid carbon dioxide. Conversion from the liquid phase to the gaseous phase is achieved at elevated temperature and pressure. The critical point is the change from liquid to gas 'without change of volume'. In reality, the volume change is minimized but it does occur, and this must be considered when finally viewing the sample.

It would be preferred that the specimen could be viewed without preparation, and for this reason cryostages and environmental chambers exist. As mentioned previously, it is possible to freeze-fracture tissue to reveal the internal structure, but it is

possible also to fracture the critical-point-dried sample, which will be very brittle. The resultant image is limited only by the fixation method.

Only the most commonly used techniques have been described, and it is inevitable that each specialized requirement will modify or create a new method.

## Introduction

Scanning electron microscopy (SEM) is one of the most versatile and widely used of the surface analytical techniques as it allows both the morphology and composition of various materials in modern science to be studied. It is considered a relatively rapid,

inexpensive, and basically nondestructive approach to surface analysis. It covers a number of areas of application like biology, geology, metallurgy, semiconductor research, and catalysis. The first scanning electron microscopes-used to examine thick specimens was described by Zworykin and co-workers in 1942, but the first commercial scanning electron microscopes, based on the work of Oatley and co-workers at Cambridge University, became available only in 1965. Since then, many advances have been made owing to improvements in lens design, high-brightness electron sources, new detectors, and electronic signal processing. Nowadays there are many different types of scanning electron microscope

designed for specific purposes ranging from routine morphological studies to high-speed compositional analyses or to the study of environment-sensitive materials (e.g., environmental scanning electron microscopes). The main advantages of SEM are the high lateral resolution (1–10 nm), large depth of focus (typically 100  $\mu\text{m}$  at  $\times 1000$  magnification), and the numerous types of electron–specimen interaction that can be used for imaging or chemical analyses purposes. In contrast to transmission electron microscopes (TEMs), specimens of largely varying sizes can be examined without elaborate specimen preparation.

Owing to the rapid advances in computing power, SEM has become relatively easy. This enables development of microscopes to be focused on the analytical aspect of the problem. As a consequence, the latest generation of these instruments is increasingly being used for process and product control. This shift in the application of electron microscopes started in the semiconductor industry, where SEM is

used for automatic inspection of critical dimensions on semiconductor wafers. The user's task is to choose the optimum detector strategies and microscope settings for the problem to be analyzed. This article will discuss the different contrast formation mechanisms in SEM. The electron beam–specimen interactions are emphasized since these interactions form the basis of the signals generated.

## The Structure of the Scanning Electron Microscope

The scanning electron microscope consists of an electron–optical column mounted on a vacuum chamber (Figure 1).

An electron gun is placed on top of this column. This gun usually consists of a thermionic cathode made of tungsten or  $\text{LaB}_6$  in a triode configuration, i.e., an additional electrode (Wehnelt) between the filament and anode. The pressure in the specimen chamber is  $10^{-3}$ – $10^{-5}$  Pa. This pressure is much

**Figure 1** Schematic cross-section of a scanning electron microscope (see text for explanation of abbreviations).

lower than the saturation vapor pressure of water, requiring special preparation of water-containing biological samples. In modern instruments operating at low voltages and high magnifications, the thermionic sources are replaced by field-emission guns (FEGs), yielding a higher brightness and lower energy spread in the beam. Field-emission sources however require a better vacuum of  $10^{-7}$ – $10^{-8}$  Pa as opposed to  $10^{-4}$ – $10^{-6}$  Pa for thermionic emitters. The crossover formed in the electron gun is demagnified by a set of magnetic (or sometimes combined magnetic and electrostatic) lenses. The condenser lenses, often in combination with spray apertures, are used to change the beam divergence angle and thus the probe current. Changes in probe current in turn will result in changes in probe diameter. The objective lens is used to focus the electron beam into a fine spot on the sample surface. In state-of-the-art instruments the minimum beam diameter on the sample ranges from 1 to 10 nm in the energy range from 30 to 0.5 keV. A set of scan coils allows rastering of the focused beam across the surface. The signals generated in the specimen by the incident electron beam are monitored synchronously with the raster scan. The magnification and scan velocity are altered by changing the scan coil excitation.

Upon entering the sample, the electron beam interacts with the sample, and both electron and photon signals are generated (Figure 2).

These signals are collected by dedicated detectors, amplified, and displayed. The images can be stored on photographic material or in a computer memory (frame store). The latter option offers the possibility for further image processing and overlaying of various detector signals. In modern instruments, distributed processors, under the control of a personal

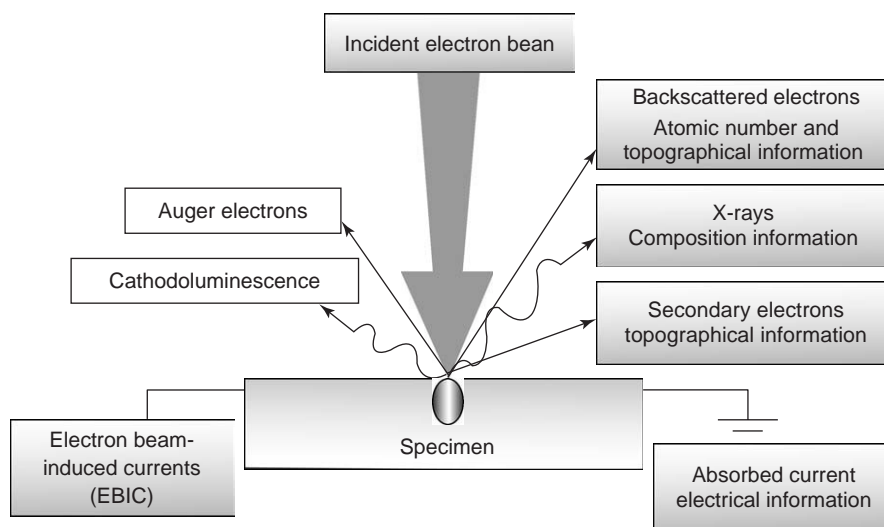

computer, operate the gun and lens power supplies, scan generator, and signal detectors.

## Electron–Optical Limits to Resolution

The lateral resolution obtainable in a scanning electron microscope is determined by two factors: (1) the incident beam diameter,  $d_p$ ; and (2) the generation volume of the signals used to obtain the image. The minimum usable beam size determined by the electron optics depends on the brightness of the gun and the electron–optical aberrations of the magnetic lenses used. The following aberrations are important in the formation of the electron beam: spherical aberration, aperture diffraction, chromatic aberration, aperture diffraction, and axial astigmatism.

### Spherical Aberration

If parallel rays are incident on an electron lens, those farther from the optical axis will be focused closer to the lens. The resulting diameter in the plane of least confusion is given by  $d_s = (1/2)C_s\alpha^3$ , where  $C_s$  is the spherical aberration coefficient, a lens parameter related to the focal length and the lens excitation, and  $\alpha$  is the aperture-limited semi-angle, which is typically  $10^{-2}$  rad and determined by a diaphragm in the polepiece gap of the objective lens. In conventional scanning electron microscopes, large working distances and weakly excited lenses are used. These lenses have large spherical aberration constants  $C_s \cong 10$ –20 mm. Small values of  $C_s \cong 1$ –2 mm can be attained by placing the specimen inside the lens field (immersion lens). These lenses are used in special high-resolution scanning electron microscopes and require in-lens detection of the secondary electrons

**Figure 2** The primary electron beam–specimen interaction in a scanning electron microscope.

since these will spiral around the magnetic field lines into the objective lens.

### Aperture Diffraction

The objective lens aperture diffracts the incident beam, enlarging the focal point into an Airy disk with half-width  $d_d = 0.6\lambda/\alpha$ . For this effect, the larger the value of  $\alpha$ , the smaller contribution of  $d_d$ . Thus, spherical aberration and aperture diffraction vary in opposite directions with  $\alpha$ . This leads to the need to find an optimum aperture angle,  $\alpha_{opt}$ , that is a balance between these two effects. For perfect lenses the diffraction error forms the physical limit to the minimum obtainable probe size. For field-emission microscopes this term becomes significant. The electron wavelength,  $\lambda$ , is given approximately by  $\lambda = 1.226/\sqrt{U}$  ( $U$  in V,  $\lambda$  in nm).

### Chromatic Aberration

The focal length of an electron lens depends on the accelerating voltage. Owing to the energy spread in the electron gun the result is a disk of least confusion with diameter  $d_c = C_c(\Delta E/E)\alpha$ , where  $C_c$  is the chromatic aberration coefficient and  $\Delta E/E$  is the fractional variation in the electron-beam energy. The value of  $C_c$  for weakly excited lenses is approximately equal to the focal length, typical 5–20 mm. Chromatic aberration, which is the largest aberration factor at low voltages ( $E < 5$  keV), can be minimized by the use of FEGs (small  $\Delta E$ ; 0.2–0.4 eV) and immersion lenses (small  $C_c$ ) and by reducing the convergence angle,  $\alpha$ . Also, very stable high-voltage and lens-current power supplies are necessary, a requirement that can be fulfilled with present-day electronic circuitry.

### Astigmatism

A final imperfection in lenses is astigmatism, which results from deviations from ideal rotational symmetry around the optical axis. Astigmatism can be caused by inhomogeneities in the polepieces, elliptical-shaped bores, charging effects in the bores, and aperture diaphragms. The effect is compensated by a stigmator, which consists of a pair of quadrupole lenses generally placed in the upper polepiece of the objective lens close to the scanning coils.

### The Minimal Probe Diameter

The geometric probe diameter,  $d_g$ , without considering lens aberrations, is limited by the apparent gun brightness,  $\beta$ . The brightness,  $\beta$ , in  $\text{A cm}^{-2} \text{sr}^{-1}$  is the most important performance indicator for electron guns. The geometrical probe diameter is related to the probe current,  $I_p$ , through  $d_g^2 = 4I_p/$

$(\pi^2\beta\alpha^2) = C_0\alpha^{-2}$ . For thermionic emitters the maximum brightness is given by  $\beta_{\max} = j_c E/(\pi k T_c)$ , where  $E$  is the accelerating (beam) energy in eV,  $k$  Boltzmann's constant ( $8.6 \times 10^{-5} \text{ eV K}^{-1}$ ),  $T_c$  the cathode temperature in K, and  $j_c$  the cathode current density in  $\text{A cm}^{-2}$ . According to this equation the brightness increases linearly with the accelerating voltage and inversely with the filament temperature. The maximum theoretical brightness of a field-emission gun is given by  $\beta_{\max} = j_c E/(\pi \Delta E)$ , where  $\Delta E$  is the energy spread of the beam. Typical values for the cathode parameters are compiled in Table 1.

Small values of  $d_g$  require small beam currents and therefore give poor signal-to-noise ratios in the images. The geometrical probe diameter,  $d_g$ , is broadened by the aforementioned lens aberrations of the objective lens, and the resulting probe diameter can be obtained from eqn [1]. For thermionic cathodes (tungsten and LaB<sub>6</sub>) the first and third terms in eqn [1] are the largest at  $E = 10$ –20 keV. For probe currents of 1–10 pA, used in high-resolution imaging, probe diameters of 5–10 nm can be attained using these guns:

$$d_p^2 = d_g^2 + d_d^2 + d_s^2 + d_c^2 \\ = [C_0^2 + (0.6\lambda)^2]\alpha^{-2} + \frac{1}{4}C_s^2\alpha^6 + \left(C_c \frac{\Delta E}{E}\right)^2 \alpha^2 \quad [1]$$

For low electron energies, however, the chromatic aberration,  $d_c$ , becomes the largest term owing to the relatively large energy spread,  $\Delta E$ . In low-voltage scanning electron microscopes, FEGs or Schottky-assisted (ZrO/W) cathodes are used. For these guns the second and last terms dominate the probe diameter, and at high voltages ( $E = 20$ –30 keV) the probe diameter becomes diffraction limited to 1–2 nm. The chromatic aberration term dominates at low voltages, limiting the probe size to 5–10 nm at  $E = 1$  kV. Chromatic aberration can be further reduced by

**Table 1** Properties of electron sources used in SEM

Parameter''	W	LaB <sub>6</sub>	Schottky ZrO/W	FEG
$T_c$ (K)	2500–3000	1400–2000	1800	300
$\phi$ (eV)	4.5	2.7	2.8	4.6
$j_c$ ( $\text{A cm}^{-2}$ )	1–3	20–50	500	$2 \times 10^5$

placing the sample in the lens field or corrected by means of multipole correctors in combination with an electrostatic retarding field lens. Theoretical calculations and laboratory experiments show that probe diameters of 2–3 nm at 1 kV are feasible.

## Depth of Focus

The depth of focus,  $T$ , is determined by the electron probe aperture,  $\alpha$ , and the magnification,  $M$ . Assuming a resolution on the cathode-ray tube or micrograph of  $d_b = 0.1$  mm (e.g., 1000 resolved lines on a 10 cm display), the corresponding lateral resolution on the specimen,  $\delta$ , is given by  $\delta = d_b/M$ . A perfectly focused beam will be geometrically broadened to a radius  $\delta/2$  at a vertical distance  $L$  given by  $L = \frac{1}{2}\delta/\tan \alpha \approx \delta/2\beta$ . The depth of field  $T$  is the vertical distance from  $-L$  to  $L$ . Thus details at a depth  $T = \delta/\alpha = d_b/\alpha M$  will appear sharp. By changing the working distance and final lens diaphragm, the electron probe aperture,  $\alpha$ , can be varied. For a typical value of  $\alpha = 10$  mrad the depth of focus varies from 1 mm at  $\times 10$  magnification to  $0.1 \mu\text{m}$  at  $\times 100\,000$  magnification. The values for the depth of focus obtainable in a scanning electron microscope are a factor of 100–1000 larger than in a light-optical microscope. Owing to its large depth of focus, the scanning electron microscope is often preferred to light microscopes at low magnifications. This is particularly true when irregularly shaped specimens with large height differences have to be observed.

## Electron Beam–Solid Interactions

When a beam electron enters a solid, it is subject to electrostatic interactions with the nuclei and electrons of the target atoms. The angle of the incident electrons is changed in the solid owing to elastic scattering by the shielded target nuclei, and the electrons lose energy owing to inelastic scattering from the core and valence electrons of the target atoms. Owing to elastic scattering events in the solid, a fraction of the incident electrons is scattered back into the vacuum. These electrons are called backscattered electrons (BSEs), and the backscatter yield,  $\eta$ , depends on the target's atomic number,  $Z$ . By convention the term BSE applies to all electrons that escape into the vacuum with energy  $E > 50$  eV.

In inelastic scattering events a primary electron ionizes target atoms. The ionized atoms fall back into a lower energy state with the emission of Auger electrons or X-rays. The energy of the X-rays is characteristic of the atom involved and is used in most scanning electron microscopes for elemental

identification. Measurements of the energies or wavelengths of these X-rays gives information about the chemical composition of the specimen. Depending on whether an energy-dispersive or wavelength-dispersive X-ray analyzer is used, the analysis technique is called EDX or WDX spectrometry. When valence electrons are involved in the inelastic scattering process, the radiation is in the visible or ultraviolet (UV) region. The technique that uses this generated light for imaging purposes in a scanning electron microscope is called cathodoluminescence (CL). The excited valence electrons created in the inelastic scattering processes are called true secondary electrons (SEs). All electrons that leave the surface with energy  $E < 50$  eV are called SEs by convention. Owing to the small mean escape depth,  $\lambda$ , of an SE ( $\lambda = 2$ – $10$  nm), only those electrons that are generated close to the surface can escape into the vacuum and be detected. This offers the possibility of obtaining high-lateral resolution SE images.

## Monte Carlo Calculations

In the Monte Carlo electron trajectory simulation, the effects of elastic and inelastic scattering are calculated from appropriate models to determine reasonable scattering angles, distances between scattering sites, and the energy loss rate. It offers the possibility of calculating the influence of the electron scattering on the signals observed in the scanning electron microscope. The calculated values for the range and resolution presented in this article are based on Monte Carlo calculation, using Mott cross-sections for the elastic scattering and appropriate inelastic cross-sections for all relevant interactions.

In **Figure 3** electron trajectories are shown for four targets of different composition at  $E = 25$  keV. The average of many electron trajectories gives an estimate of the interaction volume involved. For the heavier materials the scattering volume is approximately half a sphere with a radius equal to the

**Figure 3** Monte Carlo electron trajectory simulation for four different materials. Beam energy, 25 keV; beam diameter, 1 nm; tilt,  $0^\circ$ ; 150 trajectories. Targets (density ( $\text{g cm}^{-3}$ )): (A) carbon (2.26); (B) silicon (2.33); (C) silver (10.50); and (D) gold (19.28).

electron range. From the graphs it is also clear that in heavy materials many large-angle deflections occur, resulting in a backscatter yield,  $\eta$ , that increases with atomic number.

## Electron Range

The generation volume of BSEs and X-rays and the fraction of SEs generated by BSEs are determined by the electron range (distance traveled by the beam electrons within the solid). Because of the complex nature of the interaction volume, a number of different definitions of the electron range exist in the literature: experimental range, maximum range, Bethe range, Kanaya–Okayama range. For energies between 10 and 30 keV, as used in conventional scanning electron microscopes, the empirical range formula of Kanaya and Okayama (eqn [2]) is often used.

$$R_{K-O} = \frac{0.0276AE_0^{1.67}}{Z^{0.89}\rho} (\mu\text{m}) \quad [2]$$

where  $A$  is the relative atomic mass ( $\text{g mol}^{-1}$ ),  $E_0$  is the beam energy (keV),  $Z$  is the atomic number, and  $\rho$  is the density ( $\text{g cm}^{-3}$ ). At lower energies ( $E = 1\text{--}10$  keV) the exponent,  $n$ , of  $E_0$  is somewhat lower,  $n = 1.3\text{--}1.38$ . In this energy range the electron range expressed in mass thickness ( $\text{g cm}^{-2}$ ) is independent of  $Z$ . The electron ranges for some selected materials are shown in Table 2.

## Contrast

Contrast is defined according to eqn [3]

$$C = \frac{S_2 - S_1}{S_2}, \quad S_2 > S_1 \quad [3]$$

where  $S_1$  and  $S_2$  are the signals detected at any two arbitrarily chosen points in the scan raster that defines the image field.  $C$  is always positive, in the range between 0 and 1. The observed contrast in most SEM images is largely determined by the electron scattering and detector characteristics. Emphasis will be placed on the most often used signals from SEs and BSEs. In discussions of contrast formation,

the total SE signal is usually divided into four separate contributions (SE<sub>1</sub>–SE<sub>4</sub>).

- SE<sub>1</sub>: Generated close to the beam impact point, these electrons carry high-lateral resolution information of the order of the mean escape depth,  $\lambda$ . The obtainable lateral resolution is typically 1–5 nm.
- SE<sub>2</sub>: Generated by (B)SEs that generate SEs while escaping from the surface area. The lateral resolution due to SE<sub>2</sub> is of the order of the backscattered electron range. Typical values of the SE<sub>2</sub> range, for medium and high atomic number materials at 10–30 keV beam voltages, vary between 0.1 and 1  $\mu\text{m}$ .
- SE<sub>3</sub>: Generated by BSEs that hit the final lens polepiece and specimen chamber walls.
- SE<sub>4</sub>: Electrons created in the optical column owing to scattering from the walls and transported down the column. Good design of the column, using well-placed spray apertures, generally suppresses this contribution.

## SE Topographic Contrast

The topographic contrast observed in most SE micrographs gives these images a crisp 3D appearance (Figure 4). The observed contrast is due to a number of effects.

1. Tilt contrast. The SE yield,  $\delta$ , depends on the local tilt angle,  $\phi$ , of the surface. For voltages  $> 5$  keV the dependence of  $\delta$  on local tilt angle,  $\phi$ , is given approximately by  $\delta(\phi) = \delta_0/\cos(\phi)$ , where  $\delta_0$  is the SE coefficient at  $0^\circ$  tilt. At low voltages, when the electron range,  $R$ , becomes comparable with the mean escape depth,  $\lambda$ , of the SEs, this surface tilt contrast is greatly reduced.
2. Shadow contrast. This is the shadowing of the SE signal due to holes or protrusions. The amount of shadowing depends on the presence of electrostatic and magnetic extraction fields on the surface. Shadowing is less for detection through the lens as compared with that of the standard Everhart–Thornley detector.

**Table 2** Electron range ( $\mu\text{m}$ ) as a function of energy

$E$ (keV)	Polymer ( $C_nH_{2n+2}$ ) $\rho = 1.0 \text{ g cm}^{-3}$	$\text{SiO}_2$ $\rho = 2.20 \text{ g cm}^{-3}$	$\text{Cu}$ $\rho = 8.93 \text{ g cm}^{-3}$	$\text{Au}$ $\rho = 19.28 \text{ g cm}^{-3}$
1	0.043	0.034	0.013	0.010
3	0.28	0.18	0.056	0.041
5	0.71	0.38	0.13	0.078
10	2.2	1.3	0.39	0.20
30	15.7	8.9	2.5	1.4

**Figure 4** SE micrograph of the surface structure of cellulose.

3. Edge effect contrast. This is due to SEs that penetrate through the edges of structures. These SEs give a large additional contribution to the SE signal. This contrast is observed in most micrographs as white edges extending over a distance of the order of the electron range. Therefore, the width and magnitude of the observed edge contrast depend on the beam energy and are greatly reduced at low voltages. The edge effect gives a large SE background on which small signal fluctuations on stepped surfaces can become invisible. This effect is most disturbing when the spatial variation of the background due to the edge effect is comparable with the size of the surface structures to be examined. At high voltages this situation occurs at medium magnifications  $M = 1000\text{--}50\,000$ . Low voltages are therefore preferred when observing cross-sections or details on small topographic structures, e.g., patterns on integrated circuits (ICs). **Figure 5** shows how the edge effect observed on an IC line pattern is reduced at low voltages.

### BSE Topographic Contrast

The BSE signal also carries topographical information. The tilt dependence of the backscatter yield,  $\eta$  (tilt contrast), is less pronounced and is given empirically by

$$\eta(Z, \phi) = (1 + \cos \phi)^{-9/\sqrt{Z}} \quad [4]$$

The shadow contrast in BSE images, however, is very pronounced because the fast BSEs are not influenced by electromagnetic stray fields. They have to move in a straight line to the detector in order to be detected. To collect enough electrons, the backscatter detector has to span a large solid angle. Therefore, backscatter detectors are usually mounted under the objective lens polepiece. The backscatter signals also show some edge effects due to scattered electrons

**Figure 5** SE image of a line pattern in an IC, showing a reduced edge effect at low voltages.

that leave the edge of structures or are captured under surface steps.

The topographic contrast in BSE images can be enhanced by the use of split backscatter detectors. Subtracting the signals collected by the right and left parts of a split detector enhances the signal due to shadow or local surface tilt effects. In contrast to the situation for SEs, the BSE tilt contrast does not disappear at low voltages. The maximum obtainable resolution in topographic BSE images is determined by the range of BSEs. This range is approximately one-third to one-half of the electron range. By selection of only the nearly elastically reflected electrons, the contrast is enhanced and the lateral resolution is increased. The use of solid-state (p-n junction) or scintillator detectors enhances the high-energy fraction in the BSE signal. At low energies the penetration depth of the primary beam is of the same order as the mean escape depth of the secondary electrons. Under this condition, the lateral resolutions that can be obtained with BSEs and SEs become comparable. The use of BSEs for high-lateral resolution imaging requires sensitive detection at low voltages.

### BSE Material Contrast (Z contrast)

BSEs carry atomic number or material contrast. This is due to the fact that large-angle elastic scattering events are more probable for the heavy nuclei. This results in a strong dependence of  $\eta$  on the atomic number,  $Z$ . According to August, the backscatter yield,  $\eta$ , in the energy range  $E = 5\text{--}30\text{ keV}$  may be expressed as a power series in  $Z$  by the empirical formula:

$$\eta(E, Z) = (0.1904 - 0.2236 \ln(Z) + 0.1292 [\ln(Z)]^2 - 0.01491 [\ln(Z)]^3)(0.0002167Z + 0.987) \times E^{(0.1382 - [0.9211Z^{-1/2}])} \quad [5]$$

At high energies ( $E > 5\text{ keV}$ ) the backscatter coefficient,  $\eta$ , hardly varies with  $E$  and shows a monotonic increase with  $Z$ . At low energies ( $E < 1\text{ keV}$ )  $Z$  contrast reversal occurs.

This is a consequence of the strongly decreased elastic scattering cross-section for the high-atomic number materials at low energies. As shown by Reimer, these effects can only be predicted by extensive quantum mechanical scattering cross-section calculations based on the partial wave expansion method. For a compound material the backscatter coefficient can be obtained by weighting the elemental backscatter coefficients with their mass fractions,  $c_i$ , according to eqn [6]:

$$\eta_{\text{compound}} = \sum_i c_i \eta_i \quad [6]$$

Atomic number ( $Z$ ) contrast is very useful in the analysis of foreign materials and catalysts, contamination detection, and metallurgical phase analysis. An example of atomic number contrast is shown in Figure 6.

This micrograph shows the surface of a Ru/SiO<sub>2</sub> catalyst. The heavy ruthenium clusters appear bright, whereas the lighter silica spheres are darker in the image.

### SE Material Contrast

The SE yield,  $\delta$ , does not show a distinct atomic number dependence. Some material contrast can be observed in SE images owing to BSEs that generate SEs when leaving the specimen surface (SE<sub>2</sub>). There is also a contribution from BSEs that hit the polepiece and specimen chamber walls (SE<sub>3</sub>).

### Channeling Contrast

Through differences in crystallite orientation, grains in polycrystalline material appear with different contrast (channeling contrast). This contrast is very sensitive to small specimen tilts, and small electron probe apertures ( $\alpha = 1\text{--}10\text{ mrad}$ ) should be used. In

(A)

(B)

**Figure 6** (A) BSE micrograph of the surface of a Ru/SiO<sub>2</sub> catalyst. The backscatter image shows mainly atomic number contrast. The Ru clusters appear bright (point 1), while the lighter silica spheres are darker (point 2); (B) EDS spectrum from points 1 and 2.

contrast to topographic and atomic number contrast, a different grain orientation can result in different channeling contrast, as shown in Figure 7 for a stainless steel sample reduced at 1050°C in hydrogen.

Channeling contrast is very sensitive to amorphous surface contamination or surface oxide layers. The contrast is most pronounced on clean (chemically etched or reduced) samples at low voltages ( $E < 10\text{ keV}$ ). Energy filtering of the BSEs further enhances this contrast. Although the channeling contrast is also present in the SE signal, it is best observed in the backscatter image.

### Cathodoluminescence

Many insulating and semiconducting materials emit electromagnetic radiation in the UV, visible, or

**Figure 7** BSE image showing strong channeling contrast in a stainless steel sample.

infrared wavelengths when excited by electrons. The incident electron beam generates electrons and holes in the luminescing material. These charge carriers diffuse through the material with a characteristic diffusion length  $L$ , before they recombine with or without the emission of light. The emitted light can be collected with a parabolic or elliptical mirror situated under the polepiece and coupled to a sensitive photomultiplier. Optionally the light can be led through a monochromator or a set of color filters for wavelength selection. The image has to be acquired under slow scan conditions owing to the relatively long decay times of most luminescing materials. The luminescence observed in most materials is faint, and relatively large beam currents have to be used. Owing to the sensitivity of the luminescence to electron-beam damage, low-dose techniques should be used on organic materials. The introduction of low-voltage scanning electron microscopes with digital image collection systems and sensitive CL detectors has led to a renewed interest in the CL technique for analysis of oxides, semiconducting materials, certain minerals, and biological specimens (Figure 8).

## Absorbed Current

The absorbed current, specimen current, or target current is equal to the probe current minus the total electron emission from the sample:  $I_{\text{specimen}} = I_p(1 - \eta - \delta) = I_p(1 - \sigma)$ , where  $\sigma$  is the total electron yield, which determines the charging behavior of insulating samples. Since the absorbed current signal depends on both the SE and BSE yield, the observed contrast will be a mix of these two contributions. For most samples at high voltages,  $\eta$  is the dominant factor, and the absorbed current images will resemble the inverted backscatter images.

**Figure 8** Dependence of the total electron yield  $\sigma = \eta + \delta$  on beam energy for  $\text{SiO}_2$  at normal incidence. Positive surface charging occurs for  $\sigma > 1$  and negative charging for  $\sigma < 1$ .

Absorbed current detection is often used to detect corrosion products or different phases in metallurgic samples at relatively low magnifications.

## Electron Beam-Induced Currents

Electron beam-induced currents (EBICs) can be observed in semiconductors, p-n junctions, and Schottky barriers. An incident electron beam generates electron-hole pairs. Within or near the depletion region these charge carriers are separated by the internal field in the diode, creating an increased reverse bias current. Electron-hole pairs created far from the junction recombine according to the lifetime of the material. The average generation energy for an electron-hole pair is a few electronvolts; thus, several thousand electron-hole pairs per primary electron are generated within the scattering volume. A low-impedance current amplifier amplifies the current flow through the p-n junction. The lateral resolution is determined by the scattering volume and the minority carrier diffusion length and is of the order of micrometers. Reducing the high voltage increases the lateral resolution. All crystal defects that influence the carrier recombination are visible in the EBIC current. Accordingly the EBIC signal can be used to study diffusion lengths, surface recombination, and p-n junctions; p-n junctions can be studied parallel to the surface, in which case some depth information can be obtained by changing the beam voltage and thus the electron range.

## Conductive Coatings

Conductive coatings are applied to prevent charging of insulator specimens. For organic samples the metal film plays an additional role in the stabilization of the structure and increases the heat conduction. For

low-resolution work up to  $\times 10\,000$  magnification, sputtered gold and gold/palladium films are used.

Gold cannot be used for EDX analysis because the Au L and M peaks may interfere with the elements to be analyzed. The second disadvantage of gold coatings in X-ray analysis is the attenuation of the low-energy X-ray lines due to absorption in the gold layer. Therefore, for EDX analyses evaporated carbon films are preferred. At high magnifications (above 10 000) the island structure of gold films becomes visible. Thin continuous chromium, tungsten, or platinum films, sputter-deposited under high-vacuum conditions, are used for high-resolution imaging with field-emission scanning electron microscopes.

### Introduction

Scanning probe microscopy (SPM) is a family of related techniques that provide information about atomic scale structure and processes. The first of these to be developed was the scanning tunneling microscope (STM) by Gerd Binnig and Heinrich Rohrer at IBM Zurich in 1981. They were awarded the Nobel Prize in Physics in 1986 for their invention. Atomic force microscopy is another SPM technique invented by Gerd Binnig, Calvin Quate, and Christopher Gerber in 1986 to expand the types of surfaces on which atomic scale information can be obtained. Digital Instruments (Santa Barbara, California, USA) produced the first commercial atomic force microscope (AFM) in 1989.

These powerful techniques and others have been rapidly adopted by the scientific community and

applied in numerous fields ranging from biology to materials science. The number of publications and patents has increased exponentially over the last 20 years (**Figure 1**). SPM accounted for 8% of the microscopy market in 2002 worth US\$ 78 million and was the most rapidly growing segment.

The largest producer of SPM instruments is Veeco Instruments, Inc. (Santa Barbara, California, USA), which has acquired several AFM producers including Digital Instruments, Topometrix, and Park Scientific Instruments. Asylum Research, Pacific Nanotechnology, JEOL, Omicron NanoTechnology, and Nanonics Imaging are other major manufacturers (see **Table 1**).

### Scanning Tunneling Microscopy

The mode of operation of the STM is straightforward. An extremely sharp tip (ideally atomically sharp) is placed into close proximity with a conductive substrate. A voltage is applied between the probe tip and substrate. The gap between the two is decreased until electrons are passed from one to the

other. Current magnitude is exponentially dependent on the distance between the tip and the sample whereas the direction of current flow depends upon the orientation of the applied electric field. Once the tunneling of electrons occurs, the tip is then scanned across the sample and current levels are recorded as a function of location. A topographical map of the surface results. Tunneling energies are significantly

lower than the electron energies commonly found in scanning electron microscopy. This reduces topological artifacts caused from high-energy electrons interacting with the substrate. Scanning tunneling microscopy can be performed under ambient, liquid, or vacuum environments. Image contrast is direct; no stains or contrast agents are required. However, the sample must be conductive to be imaged.

## Instrument Components

The essential components of an STM are shown schematically in (Figure 2). A computer/user interface permits the user to control parameters such as the scan size (the range that the probe tip will travel across the sample), scan rate of the tip across the surface, and feedback control to maintain a constant height or current between the tip and substrate. The commands from the user interface are then sent to a control module that converts these commands (such as a metric scan size) into a series of voltages to be sent to the microscope. The microscope contains the sharpened tip and a scanner that moves the tip or sample in  $x$ ,  $y$ , and  $z$  directions. A sample-mounting block holds the sample rigidly in place. Rigidity is important because all SPM techniques require minimization of all sources of electrical and mechanical noise. Typically, electrical wires in the microscope are fully shielded and all mechanical components are held tightly in place. The entire microscope is mounted on an antivibration apparatus. These can range from simple homemade antivibration units such as a concrete block hanging from bungee-cords (~US\$ 100) to antivibration tables that have pneumatically suspended tabletops (>US\$ 2500). If these types of noise are not controlled or reduced, visualizing atomic-scale features is impossible.

**Piezoelectric scanners** Piezoelectrics are materials whose dimensions deform in response to an applied electric field. If the voltages that are applied to a piezoelectric are precisely controlled, extremely precise movements can be performed. The geometry of piezoelectric positioning devices used in STM includes bars, bimorphs, or tubes; tubular scanners are the most commonly used. They operate at a high resonant frequency, enabling high scan rates. Thermal isolation of the piezoelectric elements is necessary since these ceramics are also sensitive to

temperature fluctuation. The sensitivity of a piezoelectric to temperature changes is defined as:

$$\frac{\Delta x}{x_0} = \Delta \alpha * \Delta T$$

where  $x_0$  is the original dimension of the piezoelectric,  $\alpha$  the thermal expansion coefficient, and  $T$  the temperature. Piezoelectric scanners exhibit both linear and nonlinear responses to an applied voltage. As a result, careful scanner calibration is required. Scanner dimensions must be carefully matched with the desired image domain.

**STM tips** The geometry and material of the STM probe tip are critical variables required for achieving atomic-scale images. The type of material used for the STM probe varies based upon the conditions of the experiment. If one is interested in achieving atomic-scale images under ambient conditions, inert metals such as platinum or gold will suffice. A drawback of these materials is that both are very malleable and if accidental contact is made between the probe tip and the sample, the apex of the tip can be severely blunted. Thus, tungsten or platinum-iridium alloy tips are used due to their high elastic modulus. For STM experiments carried out under ultrahigh vacuum (UHV) conditions, harder materials such as iridium, molybdenum, or tungsten are typically used.

There are several methods for creating ultrasharp probes. For soft metals, tips can be fabricated mechanically by simple cutting of the probe wire (multiple attempts may be required) (Figure 3A). Probes can be sharpened by electrochemically etching the wire. The latter method will generate more consistent geometries but may also create an insulating oxide on the surface of the tip. Extremely sharp tips can be generated using a focused ion beam mill; however, the cost and availability of this tool currently precludes its widespread use. With all of these techniques, care must be taken to minimize the possibility of creating a double-tip where current is passed from multiple points between the probe and the sample. This can lead to tip-induced artifacts in the topographical image.

**Software** It is imperative that movement of the scanner be frequently calibrated. This is most often achieved by scanning a surface whose feature dimensions are accurately and precisely known. Calibration allows users to compare results from one instrument to the next and, more importantly, instills confidence in the length scales of the measured topographical features. The user must remain cognizant that they cannot visually see the sample. The image displayed is a pictorial representation of the

**Figure 2** Schematic representation of the essential components of a scanning tunneling microscope.

**Figure 3** Scanning electron micrograph of (A) mechanically sharpened platinum-iridium STM probe, (B) silicon nitride AFM cantilevers, and (C) carbon nanotube tip on silicon nitride AFM cantilever tip. (Images (A) and (B) are courtesy of Veeco Instruments; Santa Barbara, CA, USA, with permission.)

**Figure 4** A schematic depicting STM operation in (A) constant height and (B) constant current modes. In constant height mode, the tip moves horizontally over features without change in its vertical position; the change in current between the substrate and the tip ( $i_1 < i_2$ ) is recorded. In constant current mode, a feedback loop maintains a constant gap between the tip and substrate ( $d_1 = d_2$ ) by adjusting the vertical position of the tip as it moves horizontally over features.

changes in current as a function of movement in the scanner. If movement of the scanner is poorly calibrated then there is little reliability in image feature dimensions. For atomic-scale work, highly oriented pyrolytic graphite (HOPG) is a widely used calibration standard. This material is comprised of graphene sheets of carbon atoms that have hexagonal packing and well-defined carbon spacings (1.42 Å).

### Operation

Two modes are used for acquiring STM images: constant height and constant current. When the STM is operated in constant height mode, the STM probe is held at a fixed position over the sample and changes in current between the tip and the substrate (that occur when the tip travels over high or low areas) are plotted as a function of the  $x$  and  $y$  position of the scanner (Figure 4A). The constant height mode of operation can potentially lead to tip damage (also called tip crash) if the tip encounters a feature taller than the separation between the tip and the sample. When operating in constant current mode, the current between the STM tip and the conductive sample are kept constant. As the tip travels over high or low areas, changes in the scanner movement in the  $z$ -direction are plotted as a function of the  $x$  and  $y$  position of the scanner (Figure 4B). This is accomplished via the integration of a feedback loop

between the scanner and the controller. For example, when the current exceeds a preselected reference value, the controller increases the separation between the tip and the substrate until the measured current equals the reference.

### Applications

Scanning tunneling microscopy has been widely applied in research and manufacturing in fields spanning from biology to material science to microelectronics. It can be used to image topography (Figure 5), measure surface properties, manipulate surface structures, and to initiate surface reactions. The STM is an important tool in nanotechnology enabling accurate measurement of feature dimensions on the atomic scale, as well as moving and placing atomic-scale building blocks at specific locations on a surface. The latter capability makes possible the design of novel structures from single atoms or molecules.

### Atomic Force Microscopy

An AFM can achieve atomic resolution under certain conditions; however, surface features are typically resolved on the nanometer scale laterally and the angstrom scale vertically. This resolution is comparable to that of a transmission electron microscope (TEM). Resolution of the AFM depends on tip shape, scan

**Figure 5** An STM topographical image of self-assembled submonolayer of dodecanethiol chemisorbed onto an atomically flat gold surface. The 'herringbone' pattern results from the two-dimensional nucleation of the thiols on the surface (laying down of the carbon chains on the gold surface following Au–S chemical bond formation).

domain, and number of measurements per scan. Unlike many other forms of microscopy, atomic force microscopy does not require any stains, contrast agents, or conductive coatings that can cause partial obstruction of the actual sample. In addition, sample preparation is fairly simple and quick. It is a nondestructive method that allows the sample to be reused for additional analyses over time. The AFM can image a variety of materials (i.e., nonconductive, magnetic, elastic) under a variety of environmental conditions (i.e., ambient air, various gases, different humidity levels, and temperatures) and can be used to study both short- and long-range molecular and atomic forces.

## AFM Instrumentation

Atomic force microscopy measures the surface topography of a sample on a nanometer scale and the attractive and repulsive forces on a piconewton scale. An analogy can be made between AFM and a person using a cane to navigate along a landscape. The blind person strokes or taps his cane along the ground to feel where the ground is higher or lower, as well as softer or harder and rougher or smoother. In a similar fashion, the AFM measures surface topography and compliance of the sample. **Figure 6** shows a schematic of the key components of an AFM. It works by scanning a sample under an atomically sharp tip integrated on the end of a cantilever. The cantilever bends up or down as the tip contacts and is displaced by features on the surface. The most common method to measure these small movements is to use a laser beam focused on the end of the cantilever that is reflected onto a position sensitive detector. Changes in the angle of the

**Figure 6** Schematic representation of the essential components of an atomic force microscope.

cantilever induced by changes in sample topography result in different voltage levels out of the detector. These voltages are sent to a computer for processing and display of the topographic image. This scheme is the simplest and most commonly used in commercial instruments. Variations of this scheme include scanning the tip over the sample surface to allow analysis of larger samples and the use of different detectors to allow analysis of rougher samples.

## Cantilevers

Cantilevers are commercially produced from silicon and silicon nitride using microfabrication processes similar to those employed in integrated circuit manufacture. Cantilevers are often coated with metal on the topside to enhance laser reflection. There are two primary geometries of AFM cantilevers – triangular and rectangular (**Figure 3B**). Rectangular cantilevers are susceptible to torsional bending during contact mode imaging, whereas triangular cantilevers have been designed to reduce the lateral forces exerted on the cantilever.

Important cantilever specifications are their dimensions, flexibility, and resonance characteristics (resonance frequency and quality factor). The fundamental resonance frequency of the cantilever should be high in order to avoid interference from building vibrations and acoustic noise. Thermal noise from the cantilever can limit the sensitivity of the AFM and should be minimized by using shorter length cantilevers. A shorter length cantilever also provides greater angular displacement of the laser resulting in greater resolution. The spring constant ( $k$ ) of a cantilever is a measure of its flexibility. The spring constant of a rectangular cantilever is calculated from its geometry ( $w$ , width,  $l$ , length, and

$t$ , thickness) and material properties (Young's modulus,  $E$ ). The equation for the spring constant of a rectangular cantilever is

$$k = \frac{Ewt^3}{4l^3}$$

The spring constant increases with cantilever width and thickness but decreases with cantilever length. Typically stiffer cantilevers are used for dynamic imaging modes.

As in STM, the cantilever tip shape is critical to the quality of the AFM image. The overall tip geometry is often square pyramidal resulting from an etching process. The aspect ratio (height to width ratio) of the tip is important for imaging rough samples in order to fully contact recesses. The tip sharpness, or the radius of curvature at the apex, will produce artifacts in the final image. Recently, carbon nanotubes have become popular tips because of their high aspect ratio, small radius of curvature, and durability (Figure 3C). Tips are often functionalized in order to study tip to sample interactions or to conduct chemically sensitive measurements. Arrays of parallel cantilevers have been developed for use in sensor applications, data storage, and increasing scan sizes and imaging speed.

### Piezoelectric Scanner

The piezoelectric scanners used in AFM have the same characteristics as those mentioned in the STM section. The sample can be mounted directly onto the scanner and rastered underneath the cantilever tip, or the cantilever can be mounted to a scanner tube and rastered over a sample fixed below it. The former case is advantageous in imaging larger samples and increases the speed of imaging.

### Detectors

The original AFM used an STM to sense the movement of the cantilever in response to interactions with the sample. In most commercial AFM instruments, optical detectors have supplanted this type of electrical detector. The most widely used detection system uses laser beam reflection off the end of the cantilever into either a position sensitive detector or a quadrant photodiode. A change in the angle of the cantilever moves the spot on the detector, producing a change in the voltage out of the detector.

Interferometry is another detection system where a laser beam is reflected off the end of the cantilever. The phase change of the reflected laser beam is then compared to that of a standard to determine the change in cantilever position. This type of detection offers a better signal-to-noise ratio but it is more

difficult to set up and requires better vibrational and acoustic isolation.

Integration of the detector into the cantilever has also been accomplished using the piezoresistive properties of silica. This is beneficial for samples that are light sensitive and following the movements of cantilevers in an array. It can be used in conjunction with the integrated piezoelectric actuator; however, it can be difficult to decouple the signals.

## AFM Operational Modes

An AFM can be operated in several modes (contact, intermittent contact, and noncontact) to optimize topographical imaging of different types of samples, to explore different surface properties of samples, or to modify the surface.

### Contact Mode

In this mode, the probe tip is maintained in contact with the sample surface. The image can be acquired under four different imaging methods: deflection, height, friction, and force modulation. In the 'deflection method', the image is a map of cantilever bending as a function of position and is acquired under variable vertical loading forces. To image under constant applied force, the 'height method' uses a closed-loop feedback system to raise or lower the sample (or tip) to maintain a fixed cantilever deflection. The user optimizes feedback system performance by adjustment of the proportional and integral gains. Proportional gain sets the magnitude, whereas, integral gain sets the temporal response of corrective action to return the cantilever to its reference position. If the gains are too high, feedback oscillations produce image artifacts. If the gains are too low, resolution is poor due to slow response of the feedback loop.

Force curves are used to correlate vertical movement of the scanner with cantilever deflection. A typical force curve is depicted in Figure 7. Force curves are obtained by disabling the scanner movement in the  $x$  and  $y$  directions and oscillating the scanner in the  $z$ -direction. As the tip approaches the sample, no cantilever bending is observed until the gap between the tip and the sample is extremely small. Then, the cantilever will be pulled down due to the van der Waals interactions between the tip and the substrate (or by the presence of a thin hydration layer on the surface). Once in contact, raising the sample produces an upward bend in the cantilever. The applied load is computed by multiplying the reference cantilever deflection value times its spring constant. The force curve can also be used to identify adhesive

interactions between the tip and the surface. On the downward movement of the scanner, the cantilever flattens. In the presence of attractive or adhesive forces, downward deflection of the cantilever may be observed. When the restoring force of the cantilever exceeds these forces, the tip releases from the substrate surface and the cantilever returns to its original position. The magnitude of the attractive or adhesive force is calculated by multiplying the downward deflection of the cantilever times its spring constant.

The 'friction force' method measures the local variations of adhesion that may exist between the cantilever tip and the substrate. Lateral forces on the tip cause torsional bending of the cantilever that is detected by horizontal movement of the laser spot on the detector.

**Figure 7** A typical force curve acquired by monitoring cantilever deflection as the piezoelectric raises and withdraws the sample surface from the tip. The approach and retract curves are dissimilar when strong chemical and/or physical attraction between the tip and the surface exists. Illustrations of the cantilever bending at various scanner positions are depicted above and below the force curve to assist the reader in interpreting the force curve.

'Force modulation' is a contact imaging method that enables simultaneous measurement of the topology and compliance of the substrate. In force modulation, a piezoelectric actuator oscillates the cantilever chip causing the tip to slightly indent the substrate. Compliant areas on the sample will produce larger cantilever deflections compared to more rigid areas (see **Figure 8**). This is an invaluable method for characterizing the mechanical and topological properties of composite materials on the nanoscale.

### Noncontact Mode

Noncontact mode (or dynamic force) imaging relies on longer-range molecular forces to obtain surface topology. The cantilever is oscillated at its resonance frequency by a piezoactuator. The surface topography is measured by the shift in cantilever frequency based on tip/sample interactions. Specialized expertise is required to avoid image artifacts.

### Intermittent Contact Mode

Intermittent contact or TappingMode<sup>TM</sup> also oscillates the cantilever at its resonance frequency. Surface topology is measured with the height method while maintaining constant dampening of cantilever oscillation rather than cantilever deflection in contact mode. Cantilever oscillation amplitude is maintained at a fixed value using a closed-loop feedback system to raise or lower the sample (or tip). The major advantages of intermittent contact mode imaging are reduced vertical loads, lateral forces, and adhesive interactions between the tip and the substrate. This mode enables imaging of soft samples or molecules that are not strongly attached to the surface. Low drive amplitude is desired to minimize impact on soft molecules; however, it must be sufficient to overcome attractive capillary forces. This problem can be

**Figure 8** Height mode topographical (A) and force modulation (B) images of colloidal hydrogel nanoparticles immobilized on a silica substrate. Scan domain is  $12\mu\text{m} \times 12\mu\text{m}$ . Note that in the topographical image darker areas represent lower regions, whereas in the force modulation image the darker areas represent greater surface stiffness.

resolved by imaging under fluid. Imaging under fluid also provides the opportunity to examine interactions between the substrate and molecules in the liquid environment.

'Phase imaging' is an extension of intermittent contact mode that enables measurement of surface properties such as adhesion, friction, and elasticity. Phase imaging detects the phase shift of the cantilever oscillation, which is related to the surface rigidity. Phase shifts above  $90^\circ$  are due to attractive interactions, whereas phase shifts below  $90^\circ$  are due to repulsive interactions.

## AFM Applications

Atomic force microscopy has been applied to similar fields as scanning tunneling microscopy; however, AFM enables scientists to visualize non-conducting surfaces that were not possible with STM. This analytical tool enables researchers to characterize surface topology on the nanometer scale and visualize the orientation and spatial distribution of molecules adsorbed to these surfaces. Noteworthy biological applications of atomic force microscopy include the examination of drug-DNA and DNA-DNA interactions, protein conformations, enzyme reactions, and cell membrane structures (Figure 9). Applications in material science include the characterization of the surface of polymers, plastics, and coatings.

AFM has also been used to measure the mechanical properties of single molecules, molecular ensembles (membranes, cells), and surface structures. It has also enabled measurement of adhesion on the nanoscale that may exist between a chemically modified

tip and a substrate. This particular application is referred to as 'chemical force microscopy'. The experimental design for the single molecule mechanical testing is an elegant example of the chemist's ability to chemically tailor surfaces on the nanoscale. Generally these experiments are done by chemical tethering of a molecule on either a substrate or the end of the cantilever tip. The free end of the molecule possesses chemical functionality that reacts with the opposing surface. When the two surfaces are brought into close proximity, coupling of the free end of the molecule to a surface bound reactive group occurs. Pulling the two surfaces apart results in mechanical unfolding of the anchored molecule. Measurement of single molecule elasticity is afforded by analysis of the force curves generated during the pulling process. As an illustration, Figure 10 presents the repeated unfolding (tensile loading) of a polypeptide molecule using this approach.

The AFM has been employed in manufacturing and quality control of microelectronics, including semiconductor silicon wafers, MEMS devices, CDs/DVDs, and computer hard disks. The AFM is capable of identifying defects that are too small to be seen using optical microscopy.

An exciting new and evolving application of the AFM involves the manipulation of matter on the atomic scale. The AFM tip can be used to place, move, or react chemical moieties at specific locations on a surface. This can be achieved by frictional wear, controlled surface oxidation, and/or deliberate material transport between two surfaces. Material transport is unrestricted; atoms, molecules, or even cells can be attached to the AFM tip and transferred to the opposing surface at a desired location. In addition, thermal patterning of substrates can be achieved by contacting a heated cantilever tip with the surface. Potential applications include preparation of ultrahigh density data storage devices, nanoscale sensors, and molecular machines.

In summary, SPM has revolutionized our understanding of chemical phenomena on the nanoscale.

**Figure 9** AFM topographic image of a linearized plasmid DNA electrostatically immobilized on mica. This image was acquired using intermittent contact mode.

**Figure 10** Sequential force curves acquired with an AFM depicting the unfolding of an elastin-mimetic peptide.

New applications of this important nanotechnological tool will make possible the manipulation of matter on the atomic scale and enable the construction of new materials and devices for the benefit of mankind.

## Introduction

The resolution of X-ray microscopy is between the visible light microscope on the one hand and the electron microscope on the other. Instruments available today deliver about five times better resolution than visible light microscopes on a routine basis and the best achievable resolution today is 20–30 nm. The ultimate resolution of X-ray microscopy is limited, in principle, only by the wavelength:

$$\lambda = \frac{hc}{E} = \frac{1.24 \text{ keV nm}}{\text{photon energy (keV)}}$$

which is typically in the range between a tenth of a nanometer and few nanometers.

X-rays are more penetrating than electrons; further, the penetrating power of X-rays varies much more strongly with photon energy and chemical composition. As a consequence, X-ray microscopes can image samples without sectioning in the natural state and in atmospheric-pressure air. X-ray absorption edges (jumps in the absorption cross-section curve that occur when the X-ray passes the threshold energy for removing an inner-shell electron) and near-edge resonances enable the mapping of both chemical elements and their chemical binding states.

Although the intrinsic advantages of X-rays have long been recognized, their full potential for imaging could not be realized until synchrotron X-ray sources, giving radiation of required wavelength, and high-performance X-ray microfocusing optics were developed.

The history of X-ray microscopy goes back to 1896, the year following to discovery of X-rays by Roentgen. The method used for studying the structural details of biological objects by enlargement of X-ray radiographs was called ‘microradiography’ by P. Goby in 1913. Beginning in the late 1940s, X-ray microscopy with grazing incidence mirror optics was proposed by P. Kirkpatrick to exceed the optical microscope in resolution.

As a branch of earlier developments in electron microscopy, projection microscopy was proposed by V.E. Cosslett and became very popular since the 1950s. In the early 1970s, several groups started new technological developments of X-ray optics, mainly Fresnel zone plates, and the modern era of X-ray microscopy started. In 1974, G. Schmahl and collaborators built a full-field transmission microscope at DESY (Deutsches Elektronen Synchrotron) in Germany. J. Kirz and colleagues at NSLS (National Synchrotron Light Source) at Brookhaven National Laboratory in USA built the first scanning transmission microscope using zone plate objective in 1982. Traditionally, this type of X-ray microscopy deals with rather soft X-ray energies (100–2000 eV), in particular in the so-called water window region between the K-shell X-ray absorption edges of carbon

New applications of this important nanotechnological tool will make possible the manipulation of matter on the atomic scale and enable the construction of new materials and devices for the benefit of mankind.

## Introduction

The resolution of X-ray microscopy is between the visible light microscope on the one hand and the electron microscope on the other. Instruments available today deliver about five times better resolution than visible light microscopes on a routine basis and the best achievable resolution today is 20–30 nm. The ultimate resolution of X-ray microscopy is limited, in principle, only by the wavelength:

$$\lambda = \frac{hc}{E} = \frac{1.24 \text{ keV nm}}{\text{photon energy (keV)}}$$

which is typically in the range between a tenth of a nanometer and few nanometers.

X-rays are more penetrating than electrons; further, the penetrating power of X-rays varies much more strongly with photon energy and chemical composition. As a consequence, X-ray microscopes can image samples without sectioning in the natural state and in atmospheric-pressure air. X-ray absorption edges (jumps in the absorption cross-section curve that occur when the X-ray passes the threshold energy for removing an inner-shell electron) and near-edge resonances enable the mapping of both chemical elements and their chemical binding states.

Although the intrinsic advantages of X-rays have long been recognized, their full potential for imaging could not be realized until synchrotron X-ray sources, giving radiation of required wavelength, and high-performance X-ray microfocusing optics were developed.

The history of X-ray microscopy goes back to 1896, the year following to discovery of X-rays by Roentgen. The method used for studying the structural details of biological objects by enlargement of X-ray radiographs was called ‘microradiography’ by P. Goby in 1913. Beginning in the late 1940s, X-ray microscopy with grazing incidence mirror optics was proposed by P. Kirkpatrick to exceed the optical microscope in resolution.

As a branch of earlier developments in electron microscopy, projection microscopy was proposed by V.E. Cosslett and became very popular since the 1950s. In the early 1970s, several groups started new technological developments of X-ray optics, mainly Fresnel zone plates, and the modern era of X-ray microscopy started. In 1974, G. Schmahl and collaborators built a full-field transmission microscope at DESY (Deutsches Elektronen Synchrotron) in Germany. J. Kirz and colleagues at NSLS (National Synchrotron Light Source) at Brookhaven National Laboratory in USA built the first scanning transmission microscope using zone plate objective in 1982. Traditionally, this type of X-ray microscopy deals with rather soft X-ray energies (100–2000 eV), in particular in the so-called water window region between the K-shell X-ray absorption edges of carbon

**Table 1** Comparison of the features of different types of X-ray microscopy

Type of microscopy	Source	Energy (keV)	Mode of contrast	Optics	Resolution (nm)
<i>Full-field microscopy</i>					
Microradiography					
Contact	SR, Lab	>0.5	Absorption	–	100–1000
Inline imaging	SR	>1	Absorption/phase, XANES/EXAFS	–	500–1000
Magnified projection (no optics)	Lab	>1	Absorption/phase	–	100–500
Soft X-ray microscopy	SR, Lab	<4	Amplitude/phase, XANES	FZP	20–50
Hard X-ray microscopy	SR, Lab	>4	Amplitude/phase, XANES/EXAFS possible	FZP, CRL	100–500
<i>Scanning microscopy</i>					
Soft X-ray scanning microscopy	SR	<4	Absorption, fluorescence, XANES/EXAFS, photoemission	FZP	20–50
Hard X-ray microprobe	SR, Lab	>4	Absorption, fluorescence, XANES/EXAFS, diffraction	FZP, CRL, KB	100–1000

SR – synchrotron radiation sources; Lab – laboratory based sources; XANES – X-ray absorption near edge spectroscopy; EXAFS – extended X-ray absorption fine spectroscopy.

and oxygen at 4.4 nm and 2.3 nm where organic materials show strong absorption and phase contrast, while water is relatively nonabsorbing. This enables imaging of specimens up to  $\sim 10\ \mu\text{m}$  thick with high intrinsic contrast using X-rays with a lateral resolution down to 25 nm.

During the last years considerable progress has been made in X-ray microscopy in the hard X-ray regime ( $E > 4\ \text{keV}$ ), which was enhanced by the simultaneous development of high-brilliance, high-energy X-ray sources coupled with advances in manufacturing technologies of focusing optics. One of the key strengths of hard X-ray microscopy is the large penetration depth of hard X-rays in matter (around 1 mm), allowing one to probe the inner structure of an object without the need for destructive sample preparation. Resolution in the order of 100 nm was reached with photon energies up to 30 keV.

X-ray microscopy can be divided in two classes: full-field microscopy and scanning microscopy. There are two versions of full-field X-ray imaging and microscopy. The first version is the microradiography involving lensless imaging with parallel and conical beams. The second version is the full-field transmission X-ray microscope, which uses the same optical arrangement as conventional light and transmission electron microscopes. Such types of microscopes use optical elements like Fresnel zone plates or refractive optics as objective lenses for high-resolution imaging. Scanning microscopes usually use a focusing optics to form a finely focused spot or microprobe through which the specimen is rastered. The microscope of

choice is generally determined by the specimen and observation to be made on it. **Table 1** summarizes different types of X-ray microscopes available today.

## Interaction of X-Rays with Matter

X-rays interact with matter in three ways – elastic scattering, inelastic scattering, and absorption via photoelectric effect. Elastic or coherent scattering is caused by two processes: Thomson scattering from single atomic electrons, and Rayleigh scattering, which occurs from strongly bound electrons acting cooperatively. Inelastic, incoherent, or Compton scattering occurs from loosely bound (essentially free) electrons and involves the transfer of a small fraction of the incident X-ray energy. Absorption occurs when the X-ray photon transfers all of its energy to an inner atomic electron, thereby ionizing the atom. We are mainly interested in coherent scattering and absorption; that is, the phase shift of an incoming wave and attenuation of its amplitude.

Let us consider a material of thickness  $t$  and refractive index

$$n = 1 - \delta - i\beta \quad [1]$$

illuminated by a plane wave with amplitude  $A_0$ . If  $A_1$  is the amplitude of the transmitted wave, the amplitude transmission is given by

$$T = \frac{A_1}{A_0} = \exp\left(-\frac{2\pi}{\lambda}\beta t\right) \exp\left(i\frac{2\pi}{\lambda}\delta t\right) \exp\left(-i\frac{2\pi}{\lambda}t\right) \quad [2]$$

The first factor describes the attenuation of the amplitude of the incoming wave; the second factor describes the phase shift of incident beam caused by the object.  $\beta$  and  $\gamma$  are related to the linear absorption coefficient  $\mu = (4\pi/\lambda)\beta$  and to the phase shift per unit length  $\eta = (2\pi/\lambda)\delta$ .

The macroscopic parameters  $\beta$ ,  $\mu$ , and  $\delta$  are related to the atomic scattering factor  $f = f_1 + if_2$  by

$$\delta = \frac{r_0 \lambda^2}{2\pi} n f_1 \quad \beta = \frac{r_0 \lambda^2}{2\pi} n f_2$$

where  $r_0$  is the classical electron radius and  $n$  is the number of atoms per unit volume. The atomic scattering factor has been tabulated for all elements.  $f_1$  and  $f_2$  vary strongly with photon energy and chemical composition, and so do the linear absorption coefficient  $\mu$  and phase shift coefficient  $\eta$ .

For X-rays,  $\delta$  is very small ( $10^{-3}$ – $10^{-6}$ ) and positive, i.e., the refractive index is slightly less than unity. This property of X-rays causes a near absence of reflection at interfaces and results in very clear images, even of thick specimens. X-ray microscopic samples are amplitude objects as well phase objects and X-ray microscopy can be performed in amplitude (absorption) contrast and phase contrast. Hence, at high photon energies for low-density materials it is much more favorable to image an object in phase contrast rather than in absorption contrast. In addition to natural contrast mechanisms, X-rays can provide chemical bond mapping or trace elements mapping of many elements.

## X-Ray Optics

Ever since the discovery of X-rays the possibility of using them to image the microscopic structure of biological and nonbiological materials has been discussed. However, the practical implementation of an X-ray microscope was hampered until recently by the lack of intense sources giving radiation of required wavelength, and by the severe difficulties in the manufacturing of suitable optical components.

### Reflective Optics: Mirrors and Multilayers

Conventional mirrors, used for visible wavelength, cannot be used, because the reflectivity at normal incidence is too low; typically, less than 100 000 X-ray photons will be reflected. High reflectivity can be obtained at grazing incidence angles ( $\theta < \sqrt{\delta}$ ). To reduce the astigmatism Kirkpatrick and Baez proposed to use two spherical or cylindrical mirrors in a crossed configuration. **Figure 1** shows a geometrical arrangement of the so-called Kirkpatrick–Baez system (KB mirrors). To enhance the reflectivity the

**Figure 1** Two-mirror Kirkpatrick–Baez system.

multilayer mirrors, where the refractive index varies periodically with depth, can be used. To build such mirrors, alternative layers are evaporated or sputtered onto a blank with a thickness  $\lambda/4$  and relatively high refractive index and relatively low refractive index, respectively. The weak radiation reflected at the interfaces of the multiple layer is superimposed coherently and in phase, and can give a considerably increased reflectivity. The reflecting focusing systems can be either static, with mirrors polished according to the proper figure optimized for a given incidence angle and focus, or it can be dynamic, with actuators bending flat mirrors into the elliptic shapes required by the experiment. Today, as a result of improved techniques for developing highly finished and perfect surfaces, ellipsoidal and paraboloidal mirrors can be manufactured to a high degree of perfection and focusing down to 100 nm spot size is achievable with KB systems.

The reflecting mirrors are able to focus X-rays over a large energy range, whereas Bragg reflecting mirrors only focus a small fraction of the radiation continuum. Within a given energy interval, as the optical properties for total reflecting optics are independent of the X-ray wavelength, the focal spot is retained while tuning the energy. Therefore, experiments requiring energy tuning, like spectroscopy, can be performed without any readjustment of the optics. However, the disadvantage of grazing incidence optics is low acceptance and it is mostly used for scanning microscopes.

### Fresnel Zone Plates

The focusing properties of zone plates were first discussed in the latter part of the nineteenth century, and Baez originally suggested their use as X-ray optical elements in 1952. In their most common form, this is circular diffraction grating that works as a lens for monochromatic light. A Fresnel zone plate consists of a series of concentric rings of radius  $r_n^2 = n\lambda F$  and the rings become narrower at larger radii until the last, finest zone of width  $\Delta r_n$  is reached (**Figure 2**). Linear, square, elliptical zone plates have also been considered, but only circular and, to a lesser extent, linear and elliptical forms have generally been used. The focusing capability is based on

**Figure 2** Fresnel zone plate.

constructive interference of the wavefront modified by passage through the zone plate. The wavefront modification is obtained through the introduction of a relative change in amplitude or phase in the beams emerging from two neighboring zones. A zone plate is called an amplitude zone plate if the focusing results from different absorption between two neighboring zones. It is called a phase zone plate if the phase change upon transmission through a zone is the mechanism for focusing.

Just as the Rayleigh resolution of a light microscope lens is determined by its numerical aperture, NA, the Rayleigh resolution of a zone plate is determined by its maximum diffraction angle  $NA = \lambda / (2\Delta r_n)$ , so that the Rayleigh resolution is  $1.22\Delta r_n$ . Using state-of-the-art lithographic technologies, zone plates with last or outermost ring width of less than 20 nm can currently be fabricated. If illuminated with an X-ray beam whose spatial coherence length is equal to or greater than the diameter of the zone plate, a diffraction-limited focus can be obtained. In the soft X-ray region, zone plate efficiency is limited to  $\sim 15\%$  due to photoelectric absorption. For X-ray energies greater than 3 keV, it is, in principle, possible to produce phase zone plates with focusing efficiencies  $\sim 40\%$ .

### Refractive Lenses

Refractive lenses made of glass are among the most widely used optical components for visible light, with the wide spectrum of applications in focusing and imaging. Refractive lenses for X-rays were considered unfeasible for a long time due to the weak refraction and strong absorption. However, in 1996, it was shown that focusing by X-ray lenses is possible. Since  $(1 - \delta)$  in the index of refraction is smaller than 1, lenses must have a concave shape (Figure 3A). In order to obtain a focal length  $F$  in the range of 1 m many single lenses have to be stacked behind each other to form a compound refractive lens (CRL) as shown in Figure 3B. Fabricating the lenses from low-Z materials like Li, Be, B, C, and Al minimizes the problems associated with absorption. The focal

**Figure 3** Parabolic compound refractive lens (CRL). The individual lenses (A) are stacked to form a CRL (B).

length of such CRL with parabolic profile  $s^2 = 2Rw$  and  $N$  individual biconcave lenses is  $F = R/2N\delta$ , where  $R$  is the radius of curvature at the apex of parabola. A lens with thickness  $2w_0 + d$  has an aperture  $2R_0 = 2\sqrt{2Rw_0}$ .

Refractive lenses act as a normal conventional lens and we can apply the Gauss lens formula, which relates the source distance  $L_1$ , the image distance  $L_2$ , and the focal distance  $F$  via  $L_2 = FL_1/(L_1 - F)$ . The diffraction-limited resolution of the lens  $\Delta$  is defined by an effective aperture:  $\Delta = 0.75\lambda/2NA$ , where the numerical aperture is  $NA = A_{\text{eff}}/2L_2$ .  $A_{\text{eff}}$  is the effective aperture of the lens, reduced by photon absorption and scattering, compared with the geometrical aperture  $2R_0$ . Nowadays, the parabolic refractive lenses, made of aluminum and beryllium, are available and widely used for hard X-ray microscopy applications providing resolution in the order of 300–500 nm.

## Full-Field Microscopy

### Microradiography

**X-ray contact microscopy** Soon after Roentgen's discovery of X-rays it was shown that a position-sensitive detector could detect the transmission map of the object with which it was in close contact (Figure 4A). Radiographs of small objects were produced and examined under the light microscope. It is obvious that, if a light microscope is used, the resolution of the resultant image is limited by the resolution of the optical microscope. Various improvements have been made including the use of higher-resolution crystalline or polymer resists instead of film, and the use of scanning electron microscope to examine or enlarge the image. With the development of X-ray lithography, a high-resolution recording medium such as poly(methyl methacrylate)

**Figure 4** X-ray microradiography: (A) contact microscopy, (B) projection microscopy, and (C) inline imaging.

(PMMA) was employed. In addition, atomic force microscopy is used for a more quantitative read-out of the PMMA. Since it is a two-step process – an image formation step on the photoresist followed by a magnification of the miniature contact print formed on the resist – it is difficult to use in the study of dynamic processes. The use of flash sources such as X-ray lasers or laser-produced plasmas in addition to the use of synchrotron radiation sources increased the activity of X-ray contact imaging, allowing the capture of the image on a nanosecond time scale.

Contact X-ray microradiography or X-ray contact microscopy (XCM) has been applied to the largest range of specimens due to its simple implementation and considerable versatility. The biological sciences are the most important field of applications for XCM. The nonlinearity of resists makes the resist-based contact microscopy unsuitable for quantitative imaging, which considerably limits its application to materials science. However, quite opposite to the

resist, the photographic plates as recording media with XCM have been largely used for elemental mapping obtained by the differential technique and quantitative measurements.

As an alternative to photoresist recording, a contact microscope was developed, where a photoemissive surface is used instead of a photoresist detector. The electrons from the photoemitter pass through an electron optical column to yield a magnified image. For most specimens, however, a large loss in the resolution arises from the fact that not all parts of the specimen of finite thickness are in close contact with the detector, leading to blurring of the microradiograph by diffraction.

**X-ray projection microscopy (XPM)** Conceptually, a projection microscope is quite simple and relies on shadow enlargement from a point source of X-rays (Figure 4B). Earlier an electron microscope type column produced a small and bright electron spot that in turn created an X-ray spot of sufficient brightness and small diameter (0.1–1  $\mu\text{m}$ ) to provide useful magnification of several hundred times. For soft X-rays, Fresnel diffraction limits the resolution; however, for hard X-rays, the image resolution is determined entirely by the X-ray emitting volume and the electron beam current. The usual resolution of these instruments was not less than 0.5  $\mu\text{m}$ .

To improve the resolution of XPM it was proposed to use as X-ray source a secondary source generated by optics able to strongly demagnify the image of the primary source. KB mirrors are often used for this purpose. A single ellipsoidal mirror can focus X-rays from one focus into the other focus. However, the requirements on the shape fidelity are high and difficult to achieve.

High-energy XPM (20–200 keV) with source of 10  $\mu\text{m}$  is widely used for industrial and medical applications. Industrial applications concern the control of products (castings, ceramics, electronic components) to detect microporosities and cracks. In materials science XPM is applied to study alloys, composite materials, and dynamic phenomena. In the medical sciences the applications of XPM concerns the study of cancer lesions, evaluation of bone mineral density, and teeth studies.

At medium and low energies (1–20 keV) projection microscopy was commercially established and used in materials and geological sciences and for biological applications. Nevertheless, the technique lost its popularity because of competition from the scanning electron microscope and electron probe analyzer, both of which offer X-ray elemental fluorescence maps superimposed on structural images. However, both of these instruments give information about the

near-surface layers, so they do not replace X-ray projection microscope's potential for three-dimensional imaging. Currently, active projection microscopes are based on simple modifications of a scanning electron microscope and are used in three-dimensional imaging experiments employing tomographic reconstruction techniques. Steady improvement in X-ray source technology over the last few years allows the manufacture of X-ray microtomographs (micro-CT) based on compact sealed X-ray microfocus tubes.

**Inline imaging** X-ray imaging at high energies such as contact radiography and projection microscopy and tomography has been used for many years to nondestructively discern the features of the internal structure of the objects in materials science, biology, and medicine. In so doing the main contrast formation is an absorption that makes some limitation in imaging of low-density materials. For imaging at micrometer and submicrometer resolutions there is no way to overcome these limits except by phase contrast imaging. At high X-ray energies the phase shift term can be up to 1000 times greater the absorption. Thus, it is possible to observe phase contrast when absorption contrast is undetectable. X-rays passing through regions of different  $\delta$  pick up different relative phases, which corresponds to being refracted and produces a distorted wave front. However, for imaging in phase contrast and to resolve phase variation across the beam a setup with a large lateral coherence length, which is favored by a small source size, is needed. For this reason, imaging in phase contrast was improved with the advent of the undulator sources at third-generation SR sources like ESRF, SPring 8, and APS. In the simple inline geometry (Figure 4C), an object is illuminated by a distant small X-ray source, which generates an almost parallel beam. A typical source-sample distance  $L_1$  is 30–50 m. The X-rays emerging from the sample at their various angles will propagate through the free space until they reach the detector. With the detector immediately behind the sample ( $L_2 = 0$ ), one will get a conventional absorption image. If the detector is placed at some distance behind the sample, we will observe the interference pattern as different components of the beam, which having been diffracted by the sample interfere with each other on further propagation through the space. Here, a combination of imaging and diffraction effects is found, typically involving interference fringes at the edges of features. These fringes improve edge visibility. The optimum positioning of the detector for best enhancement effects varies from sample to sample, depending on the X-ray wavelength and the size of

the features of interest. This inline phase-sensitive imaging is similar to the original Gabor inline holography techniques, and was first explored at the ESRF and now routinely used for imaging various kinds of samples. Since the beam is almost parallel, the resolution of this type of microscopy is determined by the detector resolution. Normally, a resolution is below  $1\mu\text{m}$ . However, it has the advantage of being simple since it needs no optics. When the two-dimensional projection microscopy is combined with tomography a three-dimensional structure determination can be achieved. For that purpose the sample has to be rotated in small steps around an axis perpendicular to the X-ray beam and for each step a micrograph is taken. Sophisticated tomography algorithms are available, which allow reconstructing the three-dimensional geometric structure of the sample.

The same spatial coherence available at synchrotrons can also be obtained with a microfocus X-ray tube with a very small source size similar to the projection microscope but with a significant source-sample distance ( $L_1 \sim 1\text{ m}$ ). It was shown that a monochromatic beam is not necessary and the polychromatic output of the X-ray tube can be used.

### Transmission X-Ray Microscope

The full-field transmission X-ray microscope (TXRM), illustrated schematically in Figure 5, uses the same optical arrangement as conventional light and transmission electron microscopes. The basic approach is to use a high-quality imaging optics as a microscope objective to create a magnified image of the object. When the object is placed slightly outside the focal distance ( $L_1$  is slightly larger than  $F$ ) then a strongly magnified image is generated at a distance  $L_2 = L_1 F / (L_1 - F)$  with magnification  $L_2 / L_1 = F / (L_1 - F)$ . This technique offers the possibility of dynamic imaging and can be adapted for phase contrast imaging.

The basic soft TXM approach is to use a condenser zone plate to monochromatize and to concentrate X-rays onto the sample. The microobjective zone

**Figure 5** Optical schematic of transmission X-ray microscope.

plate forms a magnified real image of the sample at roughly  $1000\times$  magnification. The enlarged image is recorded on a backside-thinned CCD camera. The sample is mounted in an environmental chamber where it can be prepared between two thin foils in its natural state, including when wet. The object chamber is in the atmospheric pressure, while the major parts of the X-ray optical path are in vacuum. Image exposure times range from under a second with dry specimens to a few seconds for wet specimens, depending on the zone plate used. Phase contrast in TXRM as a full analog of Zernike phase contrast in visible light microscopy has been realized. A removal ring aperture was placed near the condenser and a phase-ring was permanently mounted in the conjugate plane. The improved contrast allowed for reduced illumination and therefore reduced radiation dose to the specimen. A cryogenic object chamber has been developed and implemented at the TXRM. The cryogenic method allows imaging of chemically unfixed samples with resolution 20–30 nm. Furthermore, the high stability of frozen-hydrated samples allows taking multiple images for tomography.

Concerning hard X-rays there are two types of optics available today with sufficient quality to be used in the development of full-field imaging: CRLs and Fresnel zone plates. Both have in common that their focal length for X-rays with photon energies  $\sim 10$  keV and higher is of order of meters, and that their apertures are limited to several hundred micrometers. The length of the setup will increase as  $M$  increasingly differs from unity. The length of the entire microscope can be in the order of 10–25 m. Another implication of long focal length is a very small numerical aperture, which limits the resolution of the imaging setup. Resolution of  $\sim 100$ –300 nm is achievable.

### Scanning X-Ray Microscope

Finally, we consider X-ray microscopy in the scanning mode, illustrated in Figure 6. The basic idea in scanning microscopy is to form a microprobe across which the specimen is mechanically scanned. A proportional counter detects the transmitted X-rays and the image is built up pixel (picture element) by pixel. The focused X-ray probe can also be used to excite other process such as photoelectrons, fluorescent X-rays. The spatial resolution is limited by the focusing optics.

**Soft X-ray transmission scanning microscope** Scanning transmission X-ray microscopes (STXRM) for soft X-rays use Fresnel zone plates as high-resolution objectives to form a focused spot. Scanning microscopes require coherent illumination and are

**Figure 6** Schematic of scanning transmission X-ray microscope.

used with high brightness sources such as undulators at synchrotron storage rings. Scanning microscopes generally have exposure times of minutes; each pixel can be formed in a few milliseconds using synchrotron radiation. But such types of microscopes impact 5–10 times less radiation dose to the specimen and have energy resolution of 0.1 eV. STXRMs are better suited to spectromicroscopy. Two main types of scanning microscopes exist today: STXRMs equipped with photon detectors and scanning photoemission microscopes equipped with electron detectors.

**Hard X-ray scanning microprobe** In the case of hard X-rays a microfocus is generated by KB mirrors, Fresnel zone plate, or parabolic CRL. The high-energy microfocusing optics benefits from longer focal lengths and larger depth of field up to a few millimeters, which is advantageous for the use of specific sample environment like furnace or high-pressure cells. A shorter wavelength is favorable for diffraction studies including wide and small angle scattering. In microprobe the strategy is to scan the beam over the sample and to measure a signal in diffraction, fluorescence, or absorption (XANES, EXAFS) for each beam position. When combining scanning microscopy with tomographic techniques the inner structure of a sample can be reconstructed, including the distribution of different atomic species and even of the valence of atoms.

### Introduction

Microwave spectroscopic techniques refer to the high-resolution absorption spectroscopy of rotational transitions of polar molecules in the gas phase. At sufficiently low pressures, of the order of a few microbars, individual transitions between quantum states become clearly separated, and their metrology using well-established radiofrequency and microwave counting methods is quite straightforward. Frequency measurements to a precision of 1 part in  $10^8$  are routine, and to several further orders of magnitude become possible with careful attention to instrumental design. As a consequence of this precision, molecular rotational spectroscopy (MRR) is highly selective, and it has been declared on many occasions that a sample compound and its isotopomers or conformers may be characterized by measurement of only a very few spectral lines, even

when the species is present in concentrations as low as nanomoles per mole, without destruction of the sample.

It will be seen in this article that the subject, written off by many as a mature technology only two decades ago, has undergone a dramatic resurgence thanks to the advent of cavity and jet spectrometry, and the ready availability of solid state and other sources together with computer control. Indeed, its characteristic use of coherent spectroscopic techniques has spread into the infrared and optical regions thanks to the production of frequency-stable diode lasers through the near- and mid-infrared, and the accessibility of data at optical wavelengths through the use of harmonic generation and the development of sensitive detectors of molecular ions.

### The Origin of Microwave Rotational Resonance Spectra

With the exception of diatomic hydrides, whose absorptions fall well into the THz region, the great majority of polar molecules show MRR spectra in

the band from 3 GHz to 1 THz. The frequency of strongest absorption varies with molecular weight and temperature, but for many species of molecular weight up to 100 a useful observing range lies between 30 and 300 GHz. Nowadays this range is well covered by commercial computer controlled synthesized frequency generators of the requisite stability, though their power output falls and their cost escalates rapidly with increasing frequency.

The intensities of typical absorptions for pure samples fall in the range  $1\text{--}10^{-8}\text{ m}^{-1}$ , much smaller than is the case for infrared or optical spectra. This is due to a number of reasons:

1. The population difference between the quantum states observed is markedly smaller than that of either alone.
2. Each state is split into numerous components by the effects of nuclear hyperfine structure, vibrational excitation, and molecular isomerism.
3. The inherent intensity of radiative transitions varies linearly with their frequency, so that at shorter wavelengths they are inevitably more intense.
4. The molecular density contributing to an absorption at microbar pressures is much less than that available for atmospheric pressure or condensed samples.

For these reasons, it is rarely practical to observe microwave or millimeterwave (mmwave) absorptions by simply following the variation of sample transmission with frequency. Rather, one seeks to modulate the absorption by switching it on and off at an audio- or radiofrequency, and to detect any resulting transmitted modulation by phase coherent detection.

In the earlier decades of microwave spectroscopy, and in all commercial spectrometers on the market at that time, the method of choice was that of Stark modulation. A uniform electric field was applied to the entire sample and switched off and on, typically at a 33 kHz rate. The resulting phase coherently detected spectral frequency scan (Figure 1) shows a spectral line in phase with the switching voltage and a number of electric-field shifted (Stark) components in antiphase with it.

Scans like these are very useful in enabling researchers to determine the molecular dipole moment as well as assigning the quantum states and positions of spectral lines. But, despite the value of such a spectrometer as a research tool, it has proved unpopular for industrial use because the high electric fields needed, up to  $0.4\text{ MV m}^{-1}$ , can produce sparking in the sample at millibar pressures leading both to sample deterioration and to an explosion hazard.

**Figure 1** A phase coherently detected Stark modulation spectrum of the  $J=3\leftarrow 2$  transition in OCS at 36488.8130 MHz. Three Stark components (negative) appear at varying distances from the unshifted spectral line (positive). (Reproduced with permission from Hollas JM (1992) *High Resolution Spectroscopy*, figure 4.13, p. 103. Chichester: Wiley; © John Wiley & Sons Ltd.)

Furthermore, the specialist absorption cells needed cannot readily be extended to give longer transit paths through the sample, and the magnitude of the Stark shift produced by a given field falls off rapidly at shorter millimeter wavelengths, greatly reducing the value of such a spectrometer in detecting and resolving lines in this more sensitive band.

Most modern general purpose spectrometers use frequency modulation, in which the source frequency is driven back and forth at an audio or higher frequency with sufficient deviation to encompass several spectral line widths. In principle, this too should reveal a coherently detected spectral profile, though usually of first- or second-derivative form, as the source is tracked through the line width. In practice, there are many new problems due to nonuniform transmission of radiation through the sample caused by discontinuities and reflections in the radiation path, as shown in Figures 2 and 3. However, these are more easily dealt with and eliminated within a computer controlled system, whilst the advantages of being able to use a hazard-free setup in which radiation may be transmitted through the atmosphere or through sequential samples are very great.

Other more specialist modulation techniques have been described in the literature; and will be discussed as appropriate in a later section.

## Appearance of Molecular Rotational Spectra

The simplest spectra are those generated from the ground vibrational state of a linear molecule. These

**Figure 2** A frequency modulation spectrum of  $K=2$ ,  $K=1$ , and  $K=0$  components of the  $J=7 \leftarrow 6$  transition of propyne,  $\text{CH}_3\text{CCH}$ , at 119.635 MHz, phase coherently detected at twice the modulation frequency, and obtained with a synchronously tuned Fabry–Perot cavity cell. (Courtesy of Wilks AT, with permission.)

**Figure 3** A frequency modulation spectrum of the  $4_{22} \leftarrow 4_{23}$  transition of HDO near 143 727 MHz, phase coherently detected at twice the modulation frequency and obtained with a synchronously tuned Fabry–Perot cavity cell. This species was present in natural abundance (270 ppm) in a sample of water vapor. The sloping background is due to the nonuniform coupling of the cavity, and may be eliminated by computer analysis. (From Alder JF and Baker JG (2002) *Quantitative Millimetre Wavelength Spectroscopy*. Cambridge: Royal Society of Chemistry; reproduced by permission of the Royal Society of Chemistry.)

consist of a ladder of almost harmonic frequencies of values  $\nu$  given by the formula:

$$\nu/(J+1) = 2B - 4D(J+1)^2$$

$J$  represents the rotational quantum number of the lower state of the absorption, and can take any integer value from zero upward.  $B$ , the rotational constant, is related to the molecular moment of

inertia  $I$  about an axis perpendicular to the linear frame by the formula:

$$B = h/8\pi^2 I \text{ (Hz)} = h/8\pi^2 I c \text{ (cm}^{-1}\text{)}$$

where  $c$  is the speed of light in  $\text{cm s}^{-1}$ .

Typical values for  $B$  can range through:

- CO 57.635 97 GHz
- HCN 44.315 80 GHz
- OCS 6.081 48 GHz

In addition, there is a centrifugal stretching contribution given by the term in  $D$ , which is some six orders of magnitude smaller than  $B$ , but which removes the exact harmonic relationship between the lines of differing  $J$  values. The practical result is that for all but the heaviest molecules only a few transitions will fall into a single conveniently accessible radiation frequency band.

The peak absorption coefficient of the transition,  $\gamma_{\text{max}}$ , if Doppler broadening is neglected, is given by

$$\gamma_{\text{max}} = f\mu^2\nu^2(1 - \exp(-h\nu/k_B T))N/\Delta\nu$$

where  $f$  is the fraction of molecules in the lower state,  $\mu$  the molecular dipole moment,  $N$  the molecular density in the sample,  $\Delta\nu$  the half-line-width (HWHM) at this density,  $h$  is Planck's constant,  $k_B$  is Boltzmann's constant, and  $T$  the temperature. Because both  $N$  and  $\Delta\nu$  are separately proportional to the pressure, this peak absorption is independent of the sample pressure over a very wide range, from a few microbars to bars. Furthermore, because  $f$  depends both on the system degeneracy  $(2J+1)$  and the thermal Boltzmann factor for the lower state, it may readily be shown that this absorption becomes largest at a frequency  $\nu_{\text{max}} = (6Bck_B T)^{1/2}$ , as illustrated in a spectral stick diagram for OCS in **Figure 4**.

At a temperature of 290 K, the maximum absorption signals for CO, HCN, and OCS occur, respectively, at 1.5 THz, 1.2 THz, and 480 GHz. Only for much heavier species would these peak frequencies fall into a centimeter wavelength band.

However, this is not the only signal that may be observed in these bands. Linear triatomic and polyatomic molecules also show skeletal bending vibrations whose frequencies are sufficiently low that they are appreciably populated at room temperatures. They form l-type doublets centered round a frequency close to but not coincident with the ground state transition. So even in the simplest case, as shown in the inset in **Figure 4** for OCS, there will appear a minimum of three spectral lines, and possibly more,

**Figure 4** A stick diagram representing the positions and intensities of the spectral lines of OCS at 290 K through the GHz and THz bands. The strongest component occurs near 480 GHz. (Inset) An expanded version representing the  $11 \leftarrow 10$  transition, and showing a pair of vibrationally excited l-type doublets shifted to frequencies above the ground state. (Courtesy of Wilks AT, with permission.)

arising from further excited vibrational or electronic states.

In nonlinear molecules spectral patterns become both more profuse and more complicated due to the existence of molecular asymmetry and the possibility of dipole moment components along any of or all three inertial axes. The reader is recommended to an appropriate text book for details of these. However, databases tabulating transition frequencies and line strengths for most abundant species of atmospheric and astrochemical interest, their isotopomers, and their low-lying vibrational states are publicly available on the internet:

- NASA database: <http://spec.jpl.nasa.gov>
- CDMS database: <http://www.ph1.uni-koeln.de/vorhersagen>
- HITRAN database: <http://cfa-www.harvard.edu.-HITRAN/>

and it should only exceptionally be necessary to carry out such calculations for oneself rather than by consulting these databases and their custodians.

## Molecular Geometries from Rotational Spectra

It is nowadays quite unusual to need to relate a molecular geometry to its inertial constants from first principles. When this is essential, procedures using the Kraitichman isotopic substitution equations, described in the reference texts, tend to give best results. However, extensive material describing structures obtained by electron diffraction as well

as by rotational spectroscopy is collated in inexpensive reference databases now available on the internet:

- MOGADOC database: <http://www.uni-ulm.de/strudo/strudo.html>

## New Techniques and Instrumentation

### Quantitative Fabry–Perot Cavity Spectrometry

A popular method for extending the path traversed by radiation through the sample is to place it between the mirrors of a confocal Fabry–Perot interferometer. Such a device allied with high-reflectivity mirrors can deliver traverses of several kilometers at frequencies ranging from tens of gigahertz to terahertz. The presence of a sample increases the cavity half-width by an amount proportional to its attenuation factor and such behavior has been shown to be capable of monitoring over a very wide frequency band by jumping between successive resonances of the interferometer. This half-width is most usually measured by carrying out and fitting frequency scans over one or several of these resonances, but an alternative procedure has been demonstrated in which the interferometer is kept resonant by servo-locking the mirror spacing to match the source frequency, and sample data are taken by scanning the depth of a frequency modulation applied to the source. Such a procedure is well adapted to the use of compact solid-state mmwave sources by obviating the need for wideband frequency scans, and has been shown to be robust and effective in monitoring samples of acrylonitrile, propyne, sulfur dioxide, oxygen, and water

present in ambient air at parts per thousand concentration. The absolute absorption coefficient is determined at the chosen source frequency, so that spectral profiles may be obtained simply by scanning this value, and the system has been shown to be capable of routine and trouble free operation in the quantitative analysis of gas mixtures at ambient pressures up to and greater than atmospheric.

The versatility of the system described above has recently been enhanced by transmitting the exciting microwave radiation as modulation on an infrared laser communications link over a fiber-optic path up to 1 km, before demodulation and harmonic generation produces a mmwave signal at the far end that drives the Fabry–Perot cell. It then acts as a mobile remote analytical spectrometer that can be moved to any convenient location whilst remaining under full control from and returning results continuously to home base.

### **Microwave–Microwave and mmwave Double Resonance**

A powerful technique for identifying and assigning spectral lines is that of double resonance, in which a sample transition is pumped by an intense amplitude modulated source, at a low frequency, and a second probed by a weaker secondary source at a higher frequency. If the two transitions have a level in common, the population difference contributing to the intensity of the probe transmission will be modulated at the frequency of the pump modulation. This is an exceedingly useful tool for disentangling complex overlapping spectra, as shown in Figure 5.

Even though the induced population changes may be quite small, the resonant pump also generates a coherence splitting of the common level that drives the probe transition transparent. So 100% amplitude modulation of the pump may be transferred to the probe when both are resonant, clearly identifying the connected systems.

The potential of this technique for the unequivocal identification of the relative abundances of constituents of a complex mixture of isotopomers, conformers, and vibrationally excited states has been remarkably little exploited. It can and has been used extensively for identifying transitions by microwave–mmwave and microwave–infrared double resonance, but not in a systematic manner.

### **Fourier-Transform Spectrometry**

The technique of applying an intense but short pulse of radiation to a sample, and then monitoring the time response of the resulting emission, has become both successful and ubiquitous in microwave

spectroscopy. The principle involved is that a short pulse of duration  $\tau$  excites all accessible transitions within a bandwidth  $1/2\pi\tau$  surrounding the pulse frequency, and that, when it is switched off, each excited state radiates coherently and separately at its own resonant frequency until its signal becomes destroyed through collision or inhomogeneous broadening effects. This is often detected by beating it with a much reduced version of the polarizing signal, after which the consequent time-resolved oscillating signal is digitized and Fourier transformed to yield the spectrum of the sample in the frequency domain.

As in the case of pulsed nuclear magnetic resonance spectrometry, this generates a signal that typically spans a range of megahertz, presents the multiplex advantage of covering many spectral features simultaneously, and can be repeated for as many shots as is necessary. But, because a typical signal decay rate lies in the region of 10 ps bar, one must work at low sample pressures using high-speed electronics. Nonetheless, the sensitivity and convenience of such machines has resulted in their steadily replacing more conventional instruments as laboratories have renewed their equipment over the past decade. Some recent published detection limits for a Fourier transform analytical spectrometer are listed in Table 1.

Extension of this technique into the more sensitive mmwave band has been foiled by a lack of broadband switches and isolators capable of functioning in this band. Attempts have been made to overcome this problem by means of two-dimensional pulsed double resonance, in which a low-frequency pump is isolated from the detector by a cutoff waveguide and the response of the probe to successive switches is digitized. Vogelsanger and Bauder have generated a two-dimensional frequency domain signal, from pump and probe, whilst an alternative procedure, in which the response to two precisely spaced pump pulses is digitized as a function of this spacing, has been described by Bowring *et al.* It enabled them to obtain Fourier transform spectra in C<sub>12</sub>N spanning as much as 75 MHz, and displaying many other nonlinear Raman beats between hyperfine components. Neither technique has seen development for chemical analysis, despite retaining the characteristic double resonance feature of distinguishing between components of complex mixtures.

### **Jet Spectroscopy**

A problem already alluded to and characteristic of rotational spectroscopy as a whole is the splitting of spectral features into many components originating in excited rotational and vibrational states. These

**Figure 5** Frequency-modulated double resonance profiles for various pumping schemes in *cis*-propionic acid. The sign displayed on the common energy level indicates whether the pump causes an increase or decrease in the population of that level. (Reproduced with permission from Stiefvater OL (1975) *Z Naturforsch* 30a: 1800.)

can largely be eliminated by expanding the sample, mixed with inert Ar, He, or Ne gas at bar pressures, through a nozzle into a high vacuum to form a highly directed supersonic jet. The expansion cools translational degrees of freedom to  $\sim 1$  K, thus greatly

reducing Doppler broadening, and rotational degrees of freedom to  $\sim 10$  K, with the result that higher  $J$  rotational transitions disappear, and lower  $J$  ones become greatly enhanced. Lower frequency vibrational states, too, tend to become depopulated.

**Table 1** Detection limits for various compounds using Fourier-transform millimeterwave spectroscopy

<sup>a</sup>Minimum detectable signal based on a 1 min average of accumulated pulses using Ne as the carrier gas.

From Suenram RG, Grabow J, Zuban A, and Leonov I (1999) A portable pulsed-molecular-beam Fourier-transform microwave spectrometer designed for chemical analysis. *Review of Scientific Instruments* 70: 2127–2135.

Because the nozzle produces a diverging beam, it is often the case that the spectra seen are split into two or more components, but this instrumental artifact is easily dealt with by computerized analysis.

Various types of nozzle have been deployed, from a simple hole to a shaped one that promotes cluster formation. It is also a common procedure to drive the nozzle through a switched magnetic valve to generate sample pulses that match the switching time of the microwave pulses. In this way one can attain higher sample densities whilst maintaining the same average pumping rate.

Although many van der Waals and cluster species of the utmost chemical interest have been characterized with such jet instruments, uncertainties in the sample density and the degree of cooling attained in an individual jet do not readily lend themselves to reproducible quantitative analysis without careful internal precalibration procedures.

### Spectroscopy of Biological Precursor Molecules

Until quite recently it was thought that such molecules were not amenable to gas-phase spectroscopic analysis, due to their involatility, their nonrigid bonding, and the presence of large numbers of overlapping conformational and vibrational states. Jet spectroscopy has changed all that. It has proved readily possible to vaporize such species at temperatures of a few hundred degree Celsius into a cool inert gas stream and to study them in a supersonic expansion. Pioneering work of this kind was carried out by Brown and Godfrey for a couple of decades

using a specially designed continuous beam Stark spectrometer, but in recent years many other groups have turned to using Fourier transform techniques with great success in determining both the nature of conformational isomers present and their detailed structures.

As an illustration, one may turn to a recent study of the alkaloid drug amphetamine. This is a phenyl- and amino-substituted propane with a total of nine possible configurations, listed in Figure 6.

The study shows that only two of these are detectable in a jet expansion (I and II), and both of them correspond to an extended rather than a folded carbon backbone chain. In contrast, X-ray diffraction structures of the same molecule in the condensed phase predict a folded chain.

### Astrochemistry

One of the greatest triumphs for microwave spectroscopy has been the detection and characterization of over 130 molecules and ions present in interstellar gas clouds, most recently the simplest amino acid glycine. Indeed, the Nobel Prize winning discovery by Curl, Kroto, and Smalley of C<sub>60</sub>, buckminsterfullerene, arose directly from microwave studies of long chain interstellar acetylenes. In 2007, a new European satellite, HERSCHEL, sensitive to signals in the terahertz band, will be launched. Who can doubt that it will give rise to many more surprising revelations about the interstellar medium?

### Analytical Chemistry

Despite the dramatic successes of the techniques described in discovering new molecular species, they have seen little success and no commercial fallout in analytical spectroscopy. Amongst the reasons that may be adduced are the difficulties in obtaining reproducible lineshape integrals in cavity spectrometry and the uncertainties in sample concentrations and temperatures in jet spectrometry. Recent work in the groups of Alder and Baker and of Krupnov has, however, demonstrated that absolute line intensities may be determined both accurately and reproducibly in a cavity spectrometer by following the effect of a sample on the cavity quality factor. Their procedure is equivalent to that of 'cavity ringdown spectroscopy' now widely used in infrared spectrometry for spectral intensity measurements. Not only does this permit of simultaneous data collection for several species, but the hyperfine and vibrational structure may be 'smeared out' by operating at pressures of 1–100 mbar, thereby enhancing the sensitivity to levels comparable with those achieved by gas chromatography. This raises the real prospect of a

**Figure 6** The nine possible configurations and calculated energies of conformers of amphetamine. Only configurations I and II appear in the observed jet spectrum. ### Introduction

Molecular emission cavity analysis (MECA) is a flame chemiluminescence technique based on the generation of excited molecules, radicals, or atoms within a hydrogen diffusion flame. The excited species are formed by direct or indirect chemiluminescence mechanisms and are confined within the inner space of a small cavity, which is positioned at a pre-selected point of the flame environment. The emission is monitored at the characteristic wavelength of

each excited species and the intensity is proportional to the concentration of analyte in the sample. The cavity is responsible for the distinct characteristics of MECA over other emission techniques into which the sample is aspirated into the flame. Hence, the cavity is the cell for the chemiluminescence reactions and promotes excitation due to chemiluminescent rather than thermal processes.

### Basic Principles

#### Hydrogen Diffusion Flame

The hydrogen diffusion flame is normally used in MECA. The flame is formed by the combustion of

### Introduction

Molecular emission cavity analysis (MECA) is a flame chemiluminescence technique based on the generation of excited molecules, radicals, or atoms within a hydrogen diffusion flame. The excited species are formed by direct or indirect chemiluminescence mechanisms and are confined within the inner space of a small cavity, which is positioned at a pre-selected point of the flame environment. The emission is monitored at the characteristic wavelength of

each excited species and the intensity is proportional to the concentration of analyte in the sample. The cavity is responsible for the distinct characteristics of MECA over other emission techniques into which the sample is aspirated into the flame. Hence, the cavity is the cell for the chemiluminescence reactions and promotes excitation due to chemiluminescent rather than thermal processes.

### Basic Principles

#### Hydrogen Diffusion Flame

The hydrogen diffusion flame is normally used in MECA. The flame is formed by the combustion of

hydrogen with atmospheric oxygen. Hydrogen is diluted with nitrogen or argon. The main reaction occurring within the flame is

The maximum temperature of the hydrogen diffusion flame does not exceed  $1000^\circ\text{C}$  since mixing of hydrogen and atmospheric oxygen is accomplished by diffusion. Hence, the amount of oxygen, which penetrates from the edges to the center of the flame body, is drastically reduced. As a result of the difficulty in mixing of oxygen with hydrogen, the temperature in the center of the flame is lower than that at the edge. The gradient of temperature is accompanied by a change in nature and a gradient of concentration of flame particles. The edge of the flame is rich in oxygen and water vapors from the main chemical reaction of the flame. The inner part of the flame is rich in atomic and unburnt hydrogen.

The ability of the hydrogen diffusion flame to act as a temperature and concentration gradient across its body can be shown with a simple experiment. If tin(II) bromide ( $\text{SnBr}_2$ ) is aspirated into the flame, then three colored regions appear (Figure 1). In region 1, the concentration of atomic hydrogen is low and the excited particles (marked with an asterisk) are formed by the reaction

This part of the flame appears green.

After deexcitation,  $\text{SnBr}$  flows to higher parts of the flame where the concentration of atomic hydrogen is higher than in region 1. Thus, region 2 appears red due to the reaction:

**Figure 1** Schematic diagram of the distribution of predominating emitting species after aspiration of tin(II) bromide in a hydrogen diffusion flame.

Unreacted  $\text{SnBr}$  from region 1 and  $\text{SnH}$  from region 2 flow upward and sideways toward the periphery of the flame. This part of the flame is rich in molecular oxygen and hydroxyl radicals and the following reactions occur:

and region 3 appears blue.

### Excitation within the Hydrogen Diffusion Flame

The emitting species are formed and stabilized in the center of the flame where the temperature is minimized. These species are produced by chemiluminescence reactions via direct mechanisms, such as:

or indirect mechanisms in which energy is transferred by or during recombination reactions, such as:

### Sample Introduction into the Hydrogen Diffusion Flame

Direct aspiration of the sample into the hydrogen diffusion flame is always associated with certain problems. The low temperature of the flame may lead to formation of solid particles, which reduce the production of emitting species and decrease sensitivity. The solvent and other components of the analyte solution may alter the temperature and disturb the radical distribution and concentration within the flame body. The distribution of the sample vapors all over the flame may be responsible for generation of more than one emitting species, such as with tin(II) bromide. Production of excited species will also be affected by the difference of temperature at various points of the flame. Moreover, the emitting species will spread over a wide region and the intensity per unit area of flame facing the detector will be low. Finally, the residence time of the analyte within the flame is short and cannot be increased since it is mainly controlled by the flow rate of the support gas.

The problems associated with aspiration of sample solution into a hydrogen diffusion flame for chemiluminescent reactions are eliminated by using the cavity for sample introduction into the flame. The use of the cavity offers the following advantages:

1. The concentration of atoms, radicals, and molecules within the inner space of the cavity can be controlled and adapted to the demands of the analysis. Thus, if the cavity is positioned at the center of

the flame, it operates within an environment of low temperature and rich in hydrogen atoms, favoring reduction and the generation of excited molecules like disulfur ( $S_2$ ) and  $Se_2$ . When the cavity is positioned at the edge of the flame, then the environment is rich in molecular oxygen and hydroxyl radicals at high temperature, favoring oxidation and formation of oxygen-containing excited species. This region can also generate atomic emissions by thermal excitation due to elevated temperatures.

2. The cavity can be cooled by a constant flow of water through its body. This allows continuous operation of the cavity within the flame and promotes emissions from species like  $S_2$  and HPO (Salet phenomenon, see below).

3. The environment of the cavity can be altered by the introduction of a gas or from the material of construction in order to select and promote specific excitation species (Table 1).

**Table 1** Emissions generated within the cavity and the most commonly used wavelengths for analytical measurement

Element	Emitting species	Wavelength (nm)
<i>Normal cavity</i>		
Gallium	GaBr	350
	Gal	391
Germanium	GeCl	455
Phosphorus	HPO	528
Selenium	$Se_2$	411
Sulfur	$S_2$	384
Tellurium	$Te_2$	500
Tin	SnO	485
Lithium	Li	670.8
Cadmium	Cd	326.1
<i>Oxy-cavity<sup>a</sup></i>		
Antimony	SbO–O continuum	355
Arsenic	AsO–O continuum	400
Boron	$BO_2$	518
Carbon	CH	431.5
Nitrogen	NO–O continuum	500
Silicon	SiO	540
Thallium	Tl	377.5
<i>Copper cavity or indium lined cavity<sup>b</sup></i>		
Bromine	CuBr	494
	InBr	375
Chlorine	CuCl	532
	InCl	360
Iodine	CuI	510
	InI	410

<sup>a</sup>A slow flow of pure oxygen is supplied to the cavity in order to promote molecular emissions from elements which require the presence of oxygen in the excited molecule or radical (such as  $BO_2$ ) or due to oxygen atom combination reactions (such as  $AsO + O \rightarrow AsO_2 + h\nu$ ).

<sup>b</sup>Both cavities promote emissions from halide-containing molecules.

## Salet Phenomenon

In 1869, Salet observed that the blue emission from sulfur compounds and the green emission from phosphorous compounds within a hydrogen flame are intensified when a cool body is introduced into the hot environment of the flame. The importance of the discovery was realized during the development of the flame photometric detector for gas chromatography and is now known as Salet phenomenon. The phenomenon is due to the stabilization of the excited molecules on the cool surface.

In MECA, the cavity acts as a cool surface and enhances the  $S_2$  emission. Nevertheless, this ability is gradually lost as the cavity heats up. This problem was overcome by designing the water-cooled cavity (Figure 2). The cavity is cooled by a constant flow of water through the body of the construction in order to allow operation at a temperature much lower than that of the flame. The temperature of the inner space of the water-cooled cavity can thus be maintained at a value of just above  $100^\circ\text{C}$ , to avoid condensation of water vapors produced by the flame reactions. This cavity design is used for continuous operation within the flame. The water-cooled cavity is the best design for making full use of the advantages of the Salet phenomenon.

## The Sulfur Emission

The generation of excited disulfur molecules by flame chemiluminescence provides an extremely sensitive way for the determination of sulfur compounds. The chemiluminogenic reactions are:

The  $S_2$  emission spectrum (Figure 3) is a typical band spectrum with maximum intensity at 384 and 394 nm. In fact, the appearance of the blue emission from a few milligrams per liter of sulfur visible by the human eye makes MECA the most sensitive technique available for the measurement of sulfur

**Figure 2** Schematic diagram of a water-cooled cavity.

**Figure 3**  $S_2$  emission spectrum from carbon disulfide vapors introduced into a water-cooled cavity into which cooling water is supplied at (A) low and (B) high flow rate, showing the effect of the Salet phenomenon on the emission (C: flame background emission). (Reproduced from Stiles DA, Calokerinos AC, and Townshend A (1994) *Flame Chemiluminescence Analysis by Molecular Emission Cavity Detection*. New York: Wiley.)

compounds. Sensitivity is further increased by the Salet phenomenon.

The emission intensity ( $I$ ) is proportional to the concentration of  $S_2$  molecules and consequently to the square of sulfur concentration  $[S]$  in the sulfur-containing analyte:

$$I \approx [S_2^*] = K[S]^2$$

where  $K$  is the reaction constant. In practice, ( $I$ ) is proportional to the  $n$ th power of the concentration of sulfur ( $I = K[S]^n$ ). The experimental values of  $n$  are within the range 1–2 and depend on the sulfur compound and measurement conditions. The exponential relation of emission intensity to sulfur concentration is responsible for the nonlinear shape of the calibration graph. The curve is linearized by plotting  $\log I$  versus  $\log C$  from which the value of  $n$  (slope) and  $K$  (intercept) can also be calculated:

$$\log I = \log K + n \log C$$

## Instrumentation

The major components of a MECA spectrophotometer are the burner, the cavity probe and holder, the optical unit, and the readout system. The only component that requires special design and careful construction is the cavity probe.

### Cavity

Extensive research on MECA has led to the development of two different procedures for using the cavity as a means for introducing the sample into

**Figure 4** Conventional MECA cavity introduction into the flame by manual rotation. (Reproduced with permission from Belcher R, Bogdanski SL, Knowles DJ, and Townshend (1975) *Analytica Chimica Acta* 77: 53–63; © Elsevier Science Publishers BV.)

the flame environment. These procedures define two different techniques: conventional MECA and gas generation MECA detection.

In conventional MECA, a liquid or solid sample is deposited into the cavity (typical dimensions: 8 mm diameter, 5 mm depth), which is then introduced rapidly and reproducibly into the flame (Figure 4).

After introduction into the flame, the cavity temperature increases from ambient to a maximum value, which depends on material and conditions. During the heat-up period of the cavity in the flame, a series of physical and chemical changes occur which are accompanied by generation of the characteristic molecular emission. A typical example of recorded response from thiourea, which generates the  $S_2$  emission, is shown in Figure 5. The cavity remains in the flame as long as required for recording the emission profile (emission intensity as a function of time). It is then removed and cooled before repetition of the process.

In gas generation MECA detection, the sample must be in the form of a gas or vapor, which is introduced into the cavity through a side duct (Figure 6). The emission is generated during passage of the gas or vapor through the cavity. The analyte is converted into a gas by a chemical reaction in a closed reactor, which is continuously purged by a carrier gas, such as nitrogen or argon.

**Figure 5**  $S_2$  emission profile at 384 nm from aqueous thiourea injected in a stainless steel cavity. (Reproduced from Stiles DA, Calokerinos AC, and Townshend A (1994) *Flame Chemiluminescence Analysis by Molecular Emission Cavity Detection*. New York: Wiley.)

**Figure 6** Schematic diagram of a gas generation MECA system for the determination of ammonium. The specific design incorporates a water-cooled cavity with a constant supply of oxygen (oxy-cavity) and is used for the generation of ammonia from ammonium samples. Ammonia is continuously purged into the cavity, reacts with oxygen and generates a bright white emission due to the NO–O reaction. (Reproduced with permission from Belcher R, Bogdanski SL, Calokerinos AC, and Townshend A (1981) *Analyst* 106: 625–635; © The Royal Society of Chemistry.)

## Conventional MECA

The processes, which occur when the cavity is positioned inside the flame by the conventional technique are:

1. Solvent evaporation.
2. Analyte evaporation by boiling, sublimation, thermal decomposition, reductive or catalytic breakdown.

3. Generation of excited species by direct or indirect chemiluminescence reactions.
4. Deexcitation and emission.

The vaporization step (2) determines the time for appearance of maximum emission intensity after the introduction of the cavity into the flame ( $t_m$ ).

The  $t_m$  value is a characteristic parameter for each compound (Table 2) but is also affected by the thermal characteristics of the cavity. The  $t_m$  value is an experimental parameter, which can be used for speciation.

A typical example of how the  $t_m$  value can be used to determine the components of a mixture is shown in Figure 7, where the  $S_2$  emission responses from a mixture containing sulfide, sulfite, and sulfate is shown. In the absence of air, sulfide and sulfite can be determined independently. The response from sulfate is then obtained by introducing air into the hydrogen diffusion flame to vaporize the refractory metal sulfate.

Typical examples of analytical applications of conventional MECA include the determination of saccharin (sulfur-containing sweetener) in soft drinks, total sulfur and sulfate in detergents, phosphate in detergents and rocks, sulfur dioxide in air, inorganic sulfate in urine, and halides in pesticides.

## Automated Conventional MECA Analyzers

Automation in conventional MECA can be achieved by positioning the cavity on a movable device. The sample is injected in the cavity automatically. The movable cavity device rotates and introduces the cavity into the flame and leads it out automatically after recording the emission.

The design can be used for the determination of phosphorus anions in inorganic samples and of sulfur compounds such as thiourea and promethazine.

A conventional flow injection MECA analyzer has been used for delivering the liquid samples to the cavity. The design is based on a flow injection system with a slow flow of carrier stream into which sulfur- and phosphorus-containing analytes are injected. The analytes are delivered to the cavity for generation of the corresponding emissions.

## Gas Generation MECA

In gas generation MECA detection, a water-cooled cavity is positioned permanently within the flame. The processes that occur are the generation of excited species, deexcitation, and emission. Therefore, the analyte must be supplied to the cavity as a gas or vapor generated from a chemical reaction and the  $t_m$

**Table 2** Typical  $t_m$  values for some sulfur anions under the same experimental conditions

Anion	$S^{2-}$	$SO_3^{2-}$	$S_2O_3^{2-}$	$SCN^-$	$SO_4^{2-}$
$t_m$ (s)	2.0	2.4	10	18	40

**Figure 7**  $S_2$  emission profiles from 5  $\mu$ l of a mixture containing sulfide, sulfite, and sulfate (as sodium salts) injected into a stainless steel cavity. (Reproduced with permission from Al-Abachi MQ, Belcher R, Bogdanski SL, and Townshend (1976) *Analytica Chimica Acta* 86: 139–146; © Elsevier Science Publishers BV.)

concept is not valid. Hence, the components of a mixture can be determined simultaneously only if they are resolved prior to introduction into the cavity, i.e., by a series of chemical reactions or via a gas chromatographic column.

The major advantages of gas generation MECA detection are:

1. Water-cooled cavities can be employed for effective use of the Salet phenomenon.
2. A great variety of chemical reactions can be used, as shown in **Table 3**.
3. The technique can be very easily automated by flow injection or continuous flow manifolds.

### Automated Gas Generation Analyzers

In the continuous flow technique, the sample is injected into the flowing reagent stream. Intermixing of individual samples is eliminated by air bubbles placed into the stream. In the flow injection technique, the sample is injected into an unsegmented continuous stream of a liquid solvent, which is then mixed with the reagent stream by diffusion and conduction. Both techniques have been successfully used in conjunction with the MECA cavity, which in this

case operates as a detector of a gas produced by a chemical reaction occurring within the flowing stream.

Typical examples of analytical applications of gas generation MECA detection include the determination of ammonium in fertilizers, fluorine in toothpaste, boron in steel samples, and thiamine and cephalosporins in pharmaceutical preparations.

### Gas and Liquid Chromatographic MECA Detection

The cavity can easily be used to detect volatile compounds as they elute from a gas chromatograph. The outlet of the column is connected to the cavity by a short stainless steel transfer tube, which is kept at the same temperature with the gas chromatographic oven.

Typical application of MECA detection after gas chromatographic separation include the separation and detection of chlorinated solvents and pesticides by using an indium-lined cavity and bromo- and iodo-compounds by using a copper water-cooled cavity.

The cavity can also be operated as a liquid chromatographic detector.

### Speciation

Since the discovery of MECA, the advantages and disadvantages of flame chemiluminescence have been

fully investigated and established. The sensitivity of MECA for sulfur-containing compounds is excellent and the selectivity can be drastically improved by using automated gas generation analyzers. The conventional technique can be used for speciation analysis based on the different  $t_m$  values of compounds, which generate the same emission within the cavity.

### Introduction

Molecular imprinting is a general strategy of synthesis that allows tailor-made polymeric materials to be obtained with memory. The concept of molecular imprinting emerged in 1940 following Linus Pauling's theory about the formation of antibodies. According to this theory, antigen molecules act as templates around which serum proteins assemble to form antibodies. Although this theory was demonstrated to be erroneous, chemists found this idea very suggestive for synthesizing materials with a certain memory for the template molecule. Following this

idea, Pauling's disciple Dickey imprinted silica gel with different dyes and obtained the first molecularly imprinted synthetic material. This experiment was repeated several years later by Sidney Bernhard.

In 1972, this approach for molecular imprinting was modified when Günter Wulff's research group developed a nonsiliceous cross-linked polymer synthesized around a template molecule. This route was also successfully followed by Shea and Thompson in 1978, who obtained a polymeric material with a predetermined spatial orientation of their functional moieties, a molecularly imprinted polymer (MIP). Both these syntheses were carried out by covalently binding the template to the functional monomer, followed by posterior polymerization of the derivatized monomer. Noncovalent approach for imprinted material synthesis was first carried out by Klaus Mosbach *et al.* in 1988. This technique of imprinting

case operates as a detector of a gas produced by a chemical reaction occurring within the flowing stream.

Typical examples of analytical applications of gas generation MECA detection include the determination of ammonium in fertilizers, fluorine in toothpaste, boron in steel samples, and thiamine and cephalosporins in pharmaceutical preparations.

### Gas and Liquid Chromatographic MECA Detection

The cavity can easily be used to detect volatile compounds as they elute from a gas chromatograph. The outlet of the column is connected to the cavity by a short stainless steel transfer tube, which is kept at the same temperature with the gas chromatographic oven.

Typical application of MECA detection after gas chromatographic separation include the separation and detection of chlorinated solvents and pesticides by using an indium-lined cavity and bromo- and iodo-compounds by using a copper water-cooled cavity.

The cavity can also be operated as a liquid chromatographic detector.

### Speciation

Since the discovery of MECA, the advantages and disadvantages of flame chemiluminescence have been

fully investigated and established. The sensitivity of MECA for sulfur-containing compounds is excellent and the selectivity can be drastically improved by using automated gas generation analyzers. The conventional technique can be used for speciation analysis based on the different  $t_m$  values of compounds, which generate the same emission within the cavity.

### Introduction

Molecular imprinting is a general strategy of synthesis that allows tailor-made polymeric materials to be obtained with memory. The concept of molecular imprinting emerged in 1940 following Linus Pauling's theory about the formation of antibodies. According to this theory, antigen molecules act as templates around which serum proteins assemble to form antibodies. Although this theory was demonstrated to be erroneous, chemists found this idea very suggestive for synthesizing materials with a certain memory for the template molecule. Following this

idea, Pauling's disciple Dickey imprinted silica gel with different dyes and obtained the first molecularly imprinted synthetic material. This experiment was repeated several years later by Sidney Bernhard.

In 1972, this approach for molecular imprinting was modified when Günter Wulff's research group developed a nonsiliceous cross-linked polymer synthesized around a template molecule. This route was also successfully followed by Shea and Thompson in 1978, who obtained a polymeric material with a predetermined spatial orientation of their functional moieties, a molecularly imprinted polymer (MIP). Both these syntheses were carried out by covalently binding the template to the functional monomer, followed by posterior polymerization of the derivatized monomer. Noncovalent approach for imprinted material synthesis was first carried out by Klaus Mosbach *et al.* in 1988. This technique of imprinting

is currently the one most used for the synthesis of such materials.

## The Molecular Imprinting Process

The memory that imprinted polymers exhibit for a particular molecule is created in the synthesis process as a result of interactions of the molecule with functional monomers. The process may be summarized in three main steps (Figure 1A):

1. Prearrangement step (complex formation), where the template associates with the functional monomer(s) forming an adduct or a polymerizable derivative.
2. Cross-linking step, in which the polymerizable derivative or the adduct copolymerizes or polymerizes with an excess of a cross-linking agent in an inert solvent, by thermal or photochemical radical initiation.
3. Washing step, where the template molecule is removed from the polymer by washing it with a

suitable solvent, usually with Soxhlet extraction, or by basic or acid hydrolysis.

The last step leaves a polymer matrix with cavities, or imprints, that are complementary in shape, size, position of the functional groups, and electronic environment to the template. Due to the rigid cross-linked structure of this imprinted material, selective rebinding and recognition of template is possible through a process similar to the lock-and-key fit (Figure 1B). There are two general imprinting strategies: the preorganized imprinting method (covalent approach) and the self-assembly imprinting method (noncovalent approach).

In the covalent approach (Figure 2), a polymerizable derivative of the template is obtained by linking the template with a vinyl functional monomer via a strong reversible covalent bond (e.g., boronate esters, Schiff bases, or ketal). The derivatized print molecule is then radical copolymerized with an excess amount of a cross-linking agent, using either thermal or photochemical radical initiation. Reaction conditions are

**Figure 1** Scheme of (A) molecular imprinting process and (B) recognition process.

**Figure 2** Covalent approach to the imprinting process.

chosen in order to stabilize the covalent bond during the polymerization. The template is finally cleaved from the imprinted sites using adequate chemical methods. Rebinding of the target molecule requires the original reversible covalent bond to reform under conditions that favor its uptake. The covalent approach results in relatively homogeneous binding sites distributed throughout the imprinted polymer. This is the result of the relatively strong covalent interactions that make possible the use of stoichiometric amounts of functional monomers with respect to the number of template molecules used. Another advantage of the covalent approach is that the polymer shows a weak dependence on the solvent used during the polymerization process. Shortcomings of the approach include the need of first preparing a monomer–template conjugate, the unavoidable chemical cleavage of the template from the polymer, and the slow rebinding kinetics. In addition, due to a lack of suitable functionality on the template, it is not always possible to prepare the polymerizable template.

The concept of noncovalent imprinting process relies on the self-assembly of functional monomers around the template in the prepolymerization mixture in a way that maximizes the binding interactions between the two species (Figure 3). These interactions between monomers and template may be of different nature: hydrogen bonding, electrostatic, hydrophobic, dipole–dipole, and/or  $\pi$ – $\pi$  interactions. After radical polymerization with a cross-linking monomer, the template is washed out with a solvent able to disrupt the noncovalent interactions between the template and the binding site. Noncovalent interactions (which are prevalent in biological systems) are exploited during both the polymerization and the rebinding processes. The main advantages of this approach are the simplicity of the synthesis, the relatively wide selection of functional monomers to choose from, the removal of the template through a simple solvent extraction process, and the rapid rebinding kinetics. MIPs prepared with a noncovalent monomer–template adduct usually contain a heterogeneous binding site population as a consequence of the low association constants, which limit the

formation of stable complexes. On the other hand, it is necessary to use an excess of functional monomer in order to shift the equilibrium toward the adduct formation that results in the random incorporation of functional monomers, many of which may not form a binding site. In spite of these limitations, at this time, most of the widely used MIPs are synthesized by radical polymerization of functional and cross-linking monomers using noncovalent interactions with the template.

## Reagents to Create a Molecularly Imprinted Polymer

The efficiency of the molecular recognition in the molecular imprinting process is affected by many parameters. Some of the main characteristics of reagents that can be used for imprinting are listed in the following.

### Templates

Molecules offering multiple site interaction for the functional monomer to ensure stable complexation often yield binding sites of higher specificity and affinity in the polymer. Because different interactions are acting simultaneously during the imprinting process, in principle there is no limit as to which print molecules can be used as templates. Thermodynamic considerations indicate that the more rigid the template, the higher the selectivity and affinity of the recognition.

From a practical viewpoint, the structure and the chemical characteristics of the template seem to be the starting point to select the imprinting approach that should be followed. For example, when noncovalent imprinting is applicable and hydrophobic interactions are desired, the solvent can be selected to enhance this effect. If acid groups are present in the target molecule, basic functional monomers should provide strong ionic interactions between the charged template and the monomer. Other forces of attraction can also be used to produce strong interactions; for example, if the print molecule is able to form metal ion complexes, then metal chelating

**Figure 3** Noncovalent approach to the imprinting process.

functional monomers should be the choice. In some instances, a combination of two functional monomers can be used with good success.

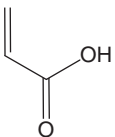

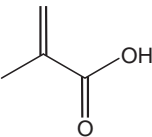

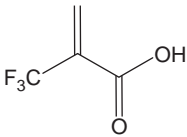

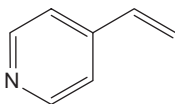

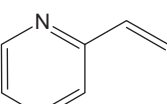

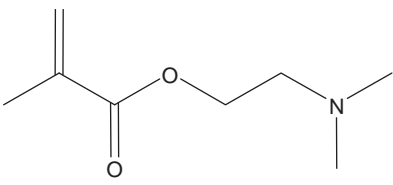

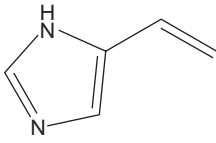

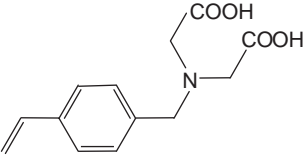

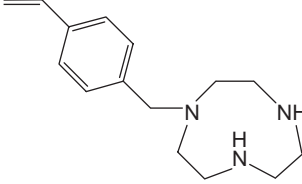

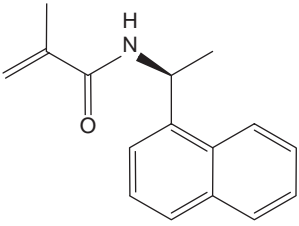

### Functional Monomers

The monomer is a key component for the synthesis of an analytically useful MIP. Its role is to provide points of electronic recognition for rebinding the template and, as stated above, its choice is often based on its capacity to form hydrogen bonds or an ion pair with the template. There is a selection of acidic, basic, neutral, metal chelating, and chiral compounds (Table 1) commercially available. Among them, methacrylic-acid-based monomers are frequently used to interact with templates having electron-donating functionalities, whereas vinylpyridine derivatives are useful as hydrogen acceptors. Chiral naphthyl monomers are expensive, but they are a good option to prepare chiral stationary phases based on imprinted polymers when no optically pure print molecules are available.

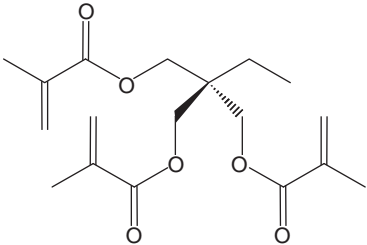

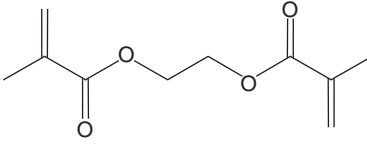

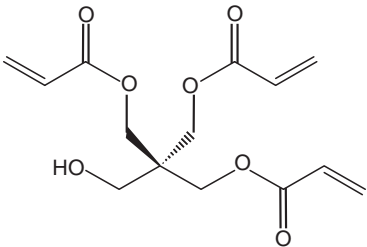

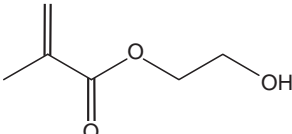

### Cross-Linker

A very high degree of cross-linking is needed in the imprinting process to achieve a very high specificity and selectivity, which is ensured by a rigid three-dimensional structure of the polymer. In order to achieve this, the functional monomer is copolymerized with a relatively large proportion of cross-linking monomer. However, the appropriate level of cross-linking agent must be optimized in order to maintain the binding specificity of the polymer. If the levels are too high, the high degree of cross-linking hinders the template diffusion into binding sites, while low levels of cross-linking may reduce rebinding because functional groups are not sufficiently fixed. On the other hand, hydrophobic/hydrophilic balance of the cross-linker determines the hydrophobic/hydrophilic nature of the MIP, which affects the extent of nonspecific binding. In general, the correct choice of the cross-linker and its proportion are often arrived at through trial and error.

**Table 1** Most common functional monomers in molecular imprinting, classified according to their functionality

Acid and hydrogen bond-forming monomers			
	Acrylic acid	Methacrylic acid	Trifluoromethyl acrylic acid
Basic functional monomers			
	4-Vinylpyridine	2-Vinylpyridine	<i>N,N</i> -Dimethylaminoethyl methacrylate
Metal chelating monomers			
	5-Vinylimidazole	4-Vinylbenzyliminodiacetic acid	1-(4'-Vinylbenzyl)-1,4,7-triazacyclononane
Chiral functional monomers			
	(S)-(-)- <i>N</i> -Methacryloyl-1-naphthylethylamine		

**Table 2** Most common cross-linkers in molecular imprinting, classified according to their nature

<i>Cross-linker</i>	<i>Name</i>	<i>Nature</i>
	Trimethylolpropane trimethacrylate	Hydrophobic
	Ethylene glycol dimethacrylate	Hydrophobic
	Pentaerythritol triacrylate	Hydrophilic
	2-Hydroxy-ethyl-methacrylate	Hydrophilic

The number of appropriate cross-linker agents is limited due to the solubility of the ‘monomerized’ template and the cross-linker itself. **Table 2** lists some cross-linker monomers. In early developments, isomers of divinylbenzene were used to cross-link styrene and other functional monomers. More recently, acrylic and methacrylic monomers have demonstrated provision for better selectivity. So, acrylic cross-linkers such as ethylene glycol dimethacrylate (EGDMA), trimethylolpropane trimethacrylate (TRIM), tri- and tetra-functional cross-linkers such as pentaerythritol triacrylate or pentaerythritol tetraacrylate are widely used. Among these EGDMA is the one most used for general imprinting purposes, and TRIM for developing imprinted stationary phases of great mechanical stability, which are useful for chromatographic systems.

#### Porogenic Solvent

The role of solvent in molecular imprinting is especially important in the prearrangement (noncovalent) approach. Solvent not only influences the polymer morphology (inner surface area and average pore

size) but also drives the strength of noncovalent interactions. Commonly, the more polar the solvent, the worse the resulting recognition, since the polarity of the solvent weakens the noncovalent interactions. In this way, the solvent should be as nonpolar as possible in order to maximize ionic interactions between the template and the functional monomer. Solvents with low hydrogen bonding basicity/acidity should be used when hydrogen bond interactions are expected to be involved. The solvent used also affects the physical characteristics of the MIP. Several studies seem to indicate that acetonitrile – a fairly polar solvent – leads to polymers with bigger pores than those prepared when chloroform is used. The solvent also influences the swelling of the polymer, but some authors have demonstrated that polymer morphology is not critical from the viewpoint of selectivity or strength in substrate rebinding.

#### Radical Initiators

Free radicals may be obtained by heating or by using UV radiation. The most common radical initiators used in molecular imprinting are the azo types and,

among them, azobisisobutyronitrile and azobisdime-thylvaleronitrile are the most important. If the template can be thermally decomposed, UV radiation at low temperature should be the reaction condition to produce free radicals. These conditions may also be desirable to improve molecular recognition when the noncovalent approach is used. However, in most cases, free radicals are produced thermally, at temperatures ranging between 60°C and 80°C.

Much of the work done on developing imprinted polymers is based on a trial and error system. New avenues are being opened to prepare these materials in a more rational way, for example, through the development of computer software programs, based on molecular dynamics and thermodynamics principles of imprinting, which are able to evaluate the most efficient functional monomer for the recognition process. In addition, the use of combinatorial chemistry approaches for synthesizing and testing a polymer library for a given template may result in high throughput systems to evaluate the best recognition material not only for the template but also for related compounds.

## MIP Configuration

Most MIP materials described to date have been prepared by the so-called monolith technique. However, it is possible to produce MIPs by different approaches, each with its advantages, shortcomings, and applications. **Figure 4** summarizes a typical synthetic procedure to obtain the polymerization

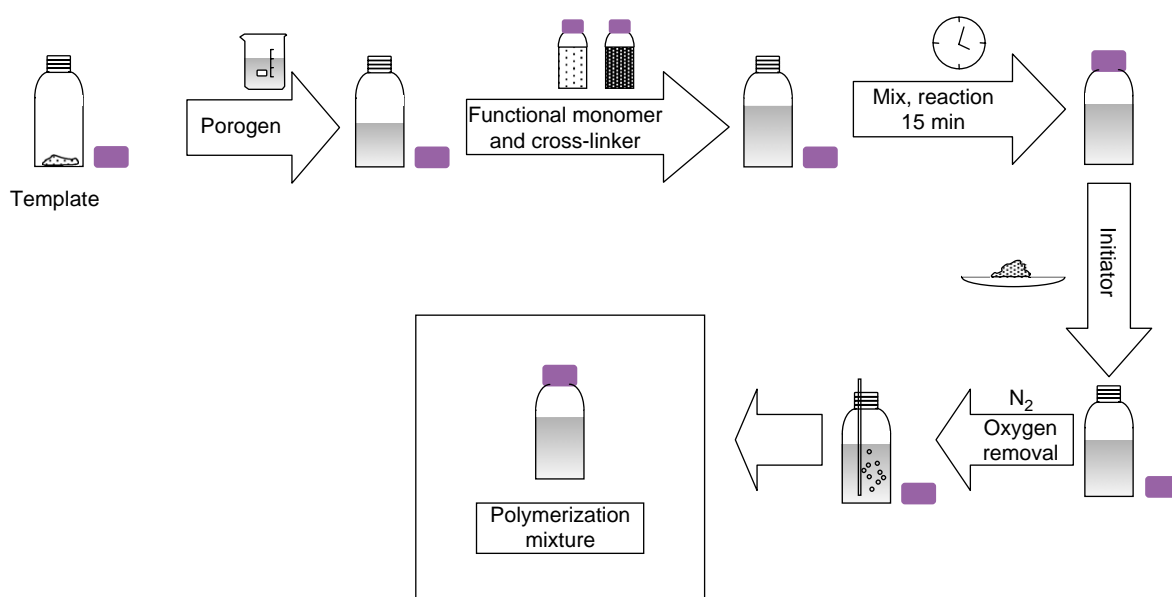

mixture. From this point, different techniques may be selected to develop the imprinted polymer.

### Monolithic Technique

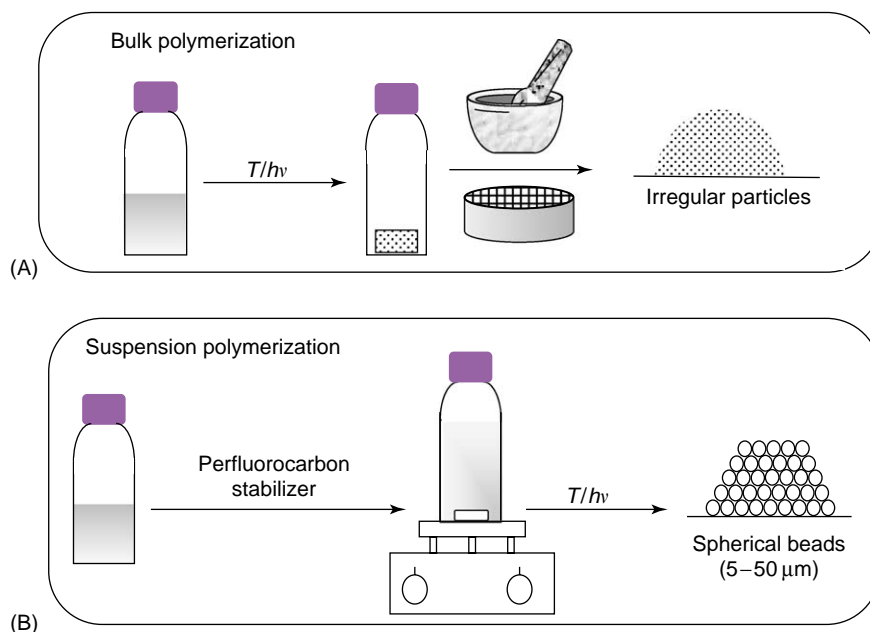

This technique refers to homogeneous solution/precipitation polymerization methods giving polymer monoliths that need to be grounded and sieved prior to use (**Figure 5A**). The main drawbacks of this approach are the loss of material in the sieving process, the large size distribution of particles, and the irregular particle shapes. Moreover, during the grinding process heat is generated, which may modify the physical characteristics of the MIP (e.g., surface area), thus creating new nonspecific binding sites. This technique is simple and most developments rely on it as the first step to demonstrate the imprinting effect and to evaluate potential applications.

### Suspension Polymerization

Some of the shortcomings of the monolithic technique, such as the irregular particle shape and the large size distribution, can be overcome by using the approach known as suspension polymerization, a fast method to synthesize spherical particles in the range of 5–50 µm. In a typical recipe, the polymerization of the emulsion of the reagents (monomer, template, cross-linker, initiator, porogenic solvent, and a suspension stabilizer) is thermally initiated upon heating and a chain reaction process takes place within the suspended globules (**Figure 5B**). Globules collide with each other, coalesce into larger ones, and

**Figure 4** Protocol for obtaining polymerization mixture, which will be polymerized later.

**Figure 5** Obtaining the monolithic and suspension presentations of the imprinting polymer.

**Figure 6** Obtaining grafted spherical particles of imprinted polymer.

rapidly break up again into smaller ones, so that their average size is the result of a dynamic process. The suspension stabilizer is necessary to avoid globule agglomeration, and perfluorocarbon liquid continuous phases have been reported to yield good-quality imprinted polymer beads with controlled particle sizes.

### Precipitation Polymerization

Particles in the submicrometer scale (typically 0.3–10  $\mu\text{m}$ ) can be obtained through this method. The synthesis is similar to the monolithic technique, but an excess of porogenic solvent is used. As particles grow, they become more insoluble in the organic solvent, and precipitation of nano- and microparticles is finally produced to form a polymer monolith. The main drawback is the larger amounts of template needed because of the dilution factor, but the particles work better than those obtained by grinding and sieving procedures. This method has been

successfully applied to prepare imprinted polymer beads for binding assays.

### Grafted Spherical Particles

In this approach, an imprinted polymer layer is grafted onto preformed spherical activated beads. Conventional supporting materials include silica particles, polystyrene and poly(TRIM) beads. While the surface of poly(TRIM) beads holds residual pendant vinyl groups, silica particles are needed to be derivatized with vinyl monomers (silane chemistry) (Figure 6). The surface groups provide the anchoring sites to incorporate the imprinted polymer layer. The technique has many advantages compared with bulk imprinted polymers: binding sites are more accessible and mass transfer and binding kinetics may be faster.

Takagi and co-workers have shown that this technique can be even performed using surfactant molecules as anchoring groups on the supporting material surface for the template molecule. Resins

imprinted by this surface approach have been prepared for metal chelation using oleic acid as a functional surfactant and oleyl-amine for catching inorganic anions such as hexacyanoferrate(II). The technique is less straightforward than one using pre-formed spherical activated beads, and its applicability to substrates of biological interest is limited due to the requirement for complexation at the aggregate-bulk solution interface.

### Imprinting at Surfaces

A number of standard techniques are available for production of MIP thin films at a surface such as a glass slide, an electrode surface, or a polymeric membrane. Spin coating, dip coating, spray coating, microcontact printing electropolymerization, chemical grafting, and physical adsorption can be chosen to synthesize thin films, depending on the nature of the surface and the specific application. For example, MIPs can be synthesized at a nonconducting surface by chemical grafting or at an electrode surface by electropolymerization. Piletsky and colleagues have described the *in situ* synthesis of a polymer, based on aminophenylboronic acid, in the presence of epinephrine (template) in the wells of a polystyrene microtiter plate. The process results in the grafting of a thin polymer layer onto the polystyrene surface and can be used in competitive enzyme-linked assays, using horseradish peroxidase-labeled norepinephrine. On the other hand, this *in situ* protocol is applicable to prepare combinatorial libraries of imprinted polymers as a robot can be easily used for automating the synthesis and evaluation of polymers.

### Sol-Gel Molecular Imprinting

The first synthetic materials with memory for a template were obtained by Dickey in 1949 using a silica gel matrix. Imprinted silica materials were produced by acid precipitation of aqueous solution of sodium silicate in the presence of dyes as templates (e.g., methyl orange). In the following years research on

imprinted silicates and metal oxide sol-gel continued and simple amorphous silicates could be imprinted for different dyes, *N*-heterocycle aromatics, proteins, and for resolution of enantiomers (e.g., camphorsulphonic acid) and stereoisomers (e.g., *N*-methyl-3-methoxymorphine, nicotine, quinine, quinidine, cinchonine, and cinchonidine). The recognition properties of these materials are dictated by the gel structure and surface chemistry, both of which are influenced by a multitude of factors, such as catalysts, pH, solvents, aging, and nature of precursors. To date, sol-gel derived molecularly imprinted materials have not revealed the same level of success as imprinted polymers for separation, catalysis, and sensor applications. One of the most unique features of imprinted sol-gel materials is their high aqueous compatible nature, allowing incorporation of biologically based guests (e.g., saccharides, peptides, proteins, drugs, and metal ions).

### Bioimprinting

Bioimprinting is predominantly used for imprinting in biopolymers, mainly proteins. The basic imprinting process was first described by Klibanov *et al.* and consisted in equilibrating a protein (subtilisin) and the template molecule (a competitive inhibitor) in aqueous buffer solution. The protein surrounds the template, and a set of weak bonds is established between them. The resulting protein-template complex was frozen, dried, and the template was removed using an organic solvent under anhydrous conditions. The imprinted enzyme was found to be several times more active than the native enzyme in anhydrous medium. Since this pioneering work of Klibanov *et al.*, different approaches have been addressed to prepare imprinted proteins and other biopolymers with specific purposes. Table 3 lists some representative examples. Although the thrust of molecularly imprinting research is focused on the development of imprints for small molecules, a new direction to develop imprints against larger structures – such as proteins, cells, and viruses – is

**Table 3** Imprinting of biomolecules and applications

<i>Biomolecule</i>	<i>Template</i>	<i>Solvent for rebinding</i>	<i>Application</i>
Bovine serum albumin	L-Malic acid	Ethyl acetate	Chromatographic separation, molecular recognition
Subtilisin Carlsberg	<i>N</i> -Acetyl-L-phenylalanine amide	Cl <sub>4</sub> C	Catalysis (transesterification reaction)
Lipase	( <i>R</i> )-1-phenyl ethanol	Isooctane	Catalysis (lauric acid esterification)
Amylose (cross-linked with cyanuric chloride)	Methylene Blue	Aqueous	Molecular recognition
Chitosan	Metal ions (Cu(II), Cd(II), Zn(II), Hg(II))	Aqueous	Ion sequestering, ion recognition

**Figure 7** Novel imprinting process for large macromolecules.

receiving attention lately. An illustrative example of such advance is the design of stable molecular recognition elements for proteins developed by Ratner *et al.* **Figure 7** shows a schematic description of the technique. A template protein (e.g., bovine serum albumin) is bound to a mica surface, as proteins adsorbed to this atomically flat material with minimal denaturalization and conformational changes. A layer of a nonreducing disaccharide was then spin-coated on the protein surface, followed by glow-discharge plasma deposition of a fluoropolymer layer in order to bind covalently the sugar molecules. The film was epoxyglued to glass and the mica sheet peeled off. Finally, the protein is removed by using an aqueous NaOH/NaOCl solution, resulting in a sugar-coated surface containing imprinted nanocavities with the size and shape of the template protein. New nanotechnologies are emerging to generate imprints for large biomolecules, cells, and microorganisms to develop new recognition materials for biological applications.

## Applications of Molecularly Imprinted Materials

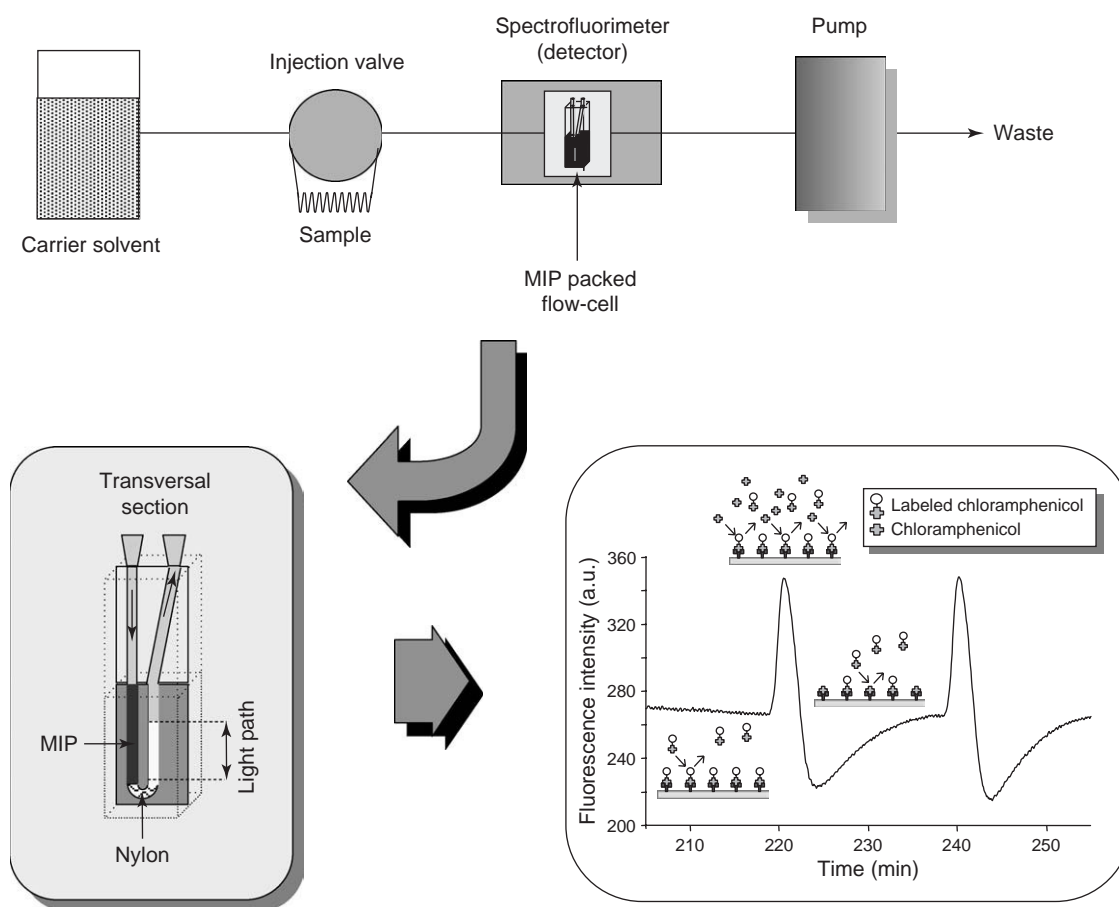

Molecularly imprinted materials can be used in many applications from synthetic chemistry as catalysts to pharmaceutical usages as drug deliverers. From an analytical point of view, imprinted polymers can be used in a variety of applications.

## Separations

MIPs are broadly used as stationary phases for high-performance liquid chromatography. An imprinted material may be *in situ* synthesized inside the chromatographic column or may be synthesized in a bulk way, grounded, sieved, and then packed into a column. At present, some companies are producing imprinted materials for solid-phase extraction (MISPE). For example, Affinity Chromatography Ltd., Ballasala, Isle of Man, is manufacturing an imprinted polymer for propranolol. MIPs as sorbents in MISPE are used to achieve selective cleanup of biological and environmental samples with high analyte enrichment factors. The MIPs can be directly used in extraction columns or cartridges in combination with existing instrumentation. Compared with immunoextraction sorbents, MIPs are stable, can be easily obtained, and have a higher adsorption capacity. A wide range of MIP materials has been examined as SPE sorbents for pesticides and compounds of biological and biomedical interest (e.g., atrazine, chlorotriazines, bentazone, propranolol, nicotine, cotinine, pentamidine,  $\beta$ -lactam antibiotics, and theophylline analogs).

## Biomimetic Assays

Due to their selectivity for the template, MIPs may be used as synthetic receptors, substituting antibodies, and biological receptors in many biochemical assays. **Figure 8** shows the principle of a continuous flow

biomimetic competitive assay for chloramphenicol. A fluorescent-labeled dummy template (a structurally related chloramphenicol molecule) competes with unlabeled template for binding to a limited amount of MIP. The chloramphenicol-imprinted polymer was placed into the flow cell, just before the optical path. A fluorescent-labeled dummy template was kept at a constant concentration in the mobile phase of the FIA system, so that recognition sites of the polymer were saturated with the fluorescent derivative. Injected samples were spiked with the labeled chloramphenicol in order to maintain its concentration constant all along the carrier stream. When samples reached the MIP, a fraction of the fluorescent derivative bound to the polymer was displaced by the chloramphenicol of the sample, yielding an increase in the fluorescence derivative concentration downstream, and a fluorescent peak was observed whose intensity was related to the total amount of chloramphenicol. Then, fluorescent-labeled dummy molecules from the carrier began to displace slowly the chloramphenicol bound to the polymer, so that the fluorescent signal decreased to a level corresponding to the amount of chloramphenicol. Finally, as the fluorescent derivative flow continued, the signal reached the baseline and the system was ready for the next assay.

### Sensors

MIPs can be used as recognition elements in sensors in the same way as other chemical or biochemical

recognition elements are used. There are different possibilities of transducing the binding event and different approaches to design the sensing system. **Table 4** depicts different transduction and configuration schemes for a variety of analytes.

### Introduction

In living organisms, the release of free radicals like superoxide or hydroxyl is usually highly cytotoxic and disruptive for normal physiological activity. The

volatile nitric oxide (NO) radical stands out as an important exception since its regulatory function in vascular tone was recognized in the late 1980s. Subsequent research has shown its regulatory and messenger function in a surprisingly wide variety of physiological processes. This small and uncharged radical has an unusually long lifetime of the order of hours in oxygenated water at physiological temperatures and undergoes very rapid diffusion. Its electrical neutrality allows NO to cross through cellular membranes easily and it partitions preferably in the

apolar lipid or protein compartment of a biological sample. In tissues, the NO lifetime can be orders of magnitude shorter due to the presence of scavenging compounds like oxyhemoglobin or superoxide and actual NO levels are determined by the continuous competition between production and consumption of NO. Under normal physiological conditions the lifetime is of the order of seconds, and the diffusion constant of  $\sim 3 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  gives NO a diffusion range of  $\sim 170 \mu\text{m}$ . As such, it spans many cell diameters, which is essential for its role in physiological signaling to cellular targets at a distance. In living organisms, the main four functions of NO are vasodilatation, neuronal signal transduction, respiratory control, and immunologic defense. In addition, metabolites of NO have been implicated in a wide variety of human diseases.

The main sources of NO are enzymatic, although nonnegligible quantities of NO may result from nonenzymatic reactions involving nitrite ions, organic nitrates, and endogenous nitrosated or nitrosylated compounds. NO can have effects either by acting directly as NO or indirectly via reactive NO metabolites. At low NO concentrations, few metabolites are formed and direct action dominates. Higher NO levels lead to a considerable release of the more reactive metabolites and indirect mechanisms dominate the physiological response. The actual NO levels vary considerably with tissue type and physiological conditions. In unstimulated tissues, NO levels are difficult to measure and seem to be in the  $10\text{--}100 \text{ nmol l}^{-1}$  range. Upon stimulation with bradykinin, calcium ionophores, or cytokines, levels may rise to  $0.1\text{--}2 \mu\text{mol l}^{-1}$ . Particularly high levels of  $1\text{--}5 \mu\text{mol l}^{-1}$  are induced by ischemia in brain tissues. Still higher levels may result from septic shock or rejection of tissue transplants (Table 1).

## Endogenous Sources of NO

In mammals, NO regulates four crucial physiological functions: vasodilatation, neuronal signal transduction, immune response against xenobiotics, and mitochondrial respiration. For each of these four functions, mammals have developed specialized isoforms of NO synthase, which synthesizes NO from the substrate L-arginine (Figure 1).

Considerable homology in the genomic structure of the isoforms suggests that they evolved from a common ancestral gene (Figure 2 and Table 2).

The endothelial (eNOS), neuronal (nNOS), and mitochondrial (mtNOS) isoforms are constitutively expressed and their NO release is controlled via the intracellular  $\text{Ca}^{2+}$  concentration and the enzyme cofactor calmodulin. Modest differences in reactivity

**Table 1** Tissue levels of NO after stimulus

Tissue	Stimulus	NO level ( $\mu\text{mol l}^{-1}$ )
Aortic endothelium	Bradykinin	0.3–1.0
Aortic smooth muscle	Bradykinin	0.1–0.8
Human veins	Bradykinin	0.01–0.1
Mesenteric arteries	Calcium ionophore	0.2–0.4
Brain	Electric	0.01–0.08
Brain	Ischemia	1.0–5.0
Mouse liver	Calcium ionophore	0.14
Mouse kidney	Calcium ionophore	0.20
Mouse placenta	Calcium ionophore	0.15

**Figure 1** Nitric oxide synthases synthesize NO by transforming L-arginine into L-citrulline in a two-step oxidation process at the heme domain. The reaction is driven by consumption of NADPH at the flavin reductase domain.

**Figure 2** Basic modular structure of all mammalian NOS isoforms. The calmodulin module is needed for electron transfer from the reductase to the heme domain and its adherence is regulated by the cytosolic  $\text{Ca}^{2+}$  concentration. The enzyme is active only in dimeric form.

to antibodies distinguish brain mtNOS from that in liver, thymus, and kidney. The gene for inducible iNOS is activated by various inflammatory cytokines, endotoxins, or lipopolysaccharides. Once formed, iNOS functions with unregulated high output and does not depend on the cytosolic  $\text{Ca}^{2+}$  concentration. Being located in mitochondria, mtNOS coexists with nNOS and eNOS in neuronal and endothelial cells, respectively. The NOS isoforms can synthesize NO only when arranged in a large protein cluster containing two NOS monomers and two calmodulin proteins and supplemented with the

**Table 2** Nomenclature and properties of the isoforms of the nitric oxide synthase enzyme

<i>Isoform</i>	<i>Acronyms</i>	<i>Activity</i>	<i>MW of human monomer (kDa)</i>	<i>Size (# amino acids)</i>	<i>Main location</i>
Endothelial NOS	eNOS, NOS III	Constitutive, $\text{Ca}^{2+}$ -regulated	133	1203	Endothelium, myocytes
Neuronal NOS	nNOS, NOS I	Constitutive, $\text{Ca}^{2+}$ -regulated	161	1434	Nerve tissue, adrenal glands, sympathetic ganglia
Mitochondrial NOS	mtNOS	Constitutive, $\text{Ca}^{2+}$ -regulated	130–145	Unknown	Mitochondria, varies with tissue type
Inducible NOS	iNOS, NOS II	Inducible, unregulated	131	1153	Macrophages, glomerulus, proximal tubule, cortical collecting duct

**Figure 3** The cascade for vasodilation in mammals. Acetylcholine or bradykinin activates endothelial membrane receptors and activates the eNOS enzyme by enhancing the intracellular calcium levels. The NO diffuses into the adjacent smooth muscle cells, where it stimulates the guanylate cyclase enzyme to produce cGMP. The latter activates protein kinase G, which stimulates outflux of  $\text{K}^+$  and  $\text{Ca}^{2+}$  from the cell. The drop in intracellular calcium triggers the relaxation of the muscle tissue. Alternatively, the guanylate cyclase in the smooth muscle cells may be activated by pharmaceutical NO donors in the bloodstream.

cofactor tetrahydrobiopterin. However, the enzyme may release substantial quantities of superoxide radicals under pathological conditions such as depletion of the substrate arginine, or after disruption of the [Zn-4S] cluster by peroxynitrite. This anomalous function is known as ‘uncoupling’ and is believed to be the initial step in a cascade leading to atherosclerosis and vascular dysfunction.

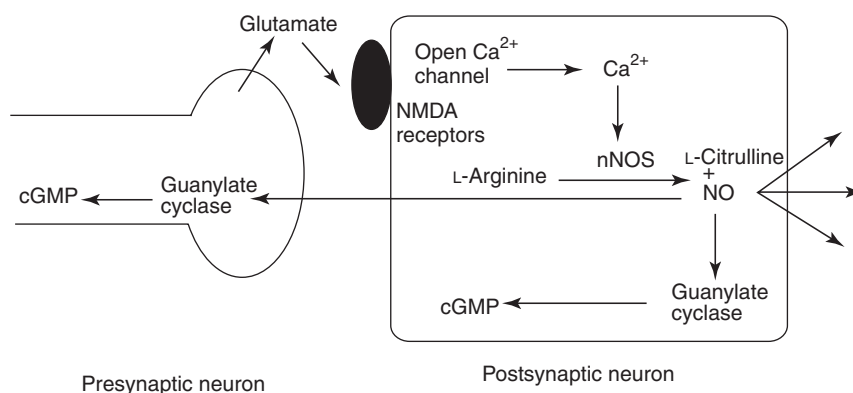

Nitrite and nitrosothiols have been identified as nonenzymatic sources of NO under physiological conditions, with a slow release of NO being catalyzed by spurious quantities of metal ions. Under normal conditions, this release is negligible with respect to enzymatic sources of NO. A possible physiological relevance for nitrosothiols as NO transporters is being discussed but controversial. Nitrate itself will release NO only under very unphysiological reductive conditions, but certain organic nitrates like

nitroglycerin may act as vasodilators in the presence of spurious metals and free cysteine.

## Physiological Targets of NO

The main function of eNOS is to trigger vasodilation by the activation of the guanylate cyclase enzyme in the smooth muscle cells of the contractile tissue surrounding the blood vessels (Figure 3). The main function of nNOS is the regulation of synaptic signal transduction between neuronal cells. The NO diffuses to adjacent neuronal cells and activates the synthesis of cGMP by the guanylate cyclase enzyme (Figure 4).

The main function of mtNOS is regulation of the mitochondrial respiration by inhibition of cytochrome C oxidase. This dimeric enzyme is located on the inner membrane of the mitochondrion and

**Figure 4** The cascade for synaptic signal transduction between neuronal cells. Release of the synaptic transmitter glutamate enhances the intracellular calcium levels and activates the nNOS enzyme. The NO can diffuse to adjacent neurons and activate the guanylate enzyme on both sides of the synaptic junction.

**Table 3** Reaction rates between NO and various physiologically relevant radical species, in aqueous environment and at room temperature

Radical	Reaction product	Reaction rate ( $\text{mol}^{-1} \text{s}^{-1}$ )	Remarks
$\text{O}_2^-$ , superoxide	$\text{ONOO}^-$	$6.7 \times 10^9$	Weak acid HOONO decomposes to nitrate
OH, hydroxyl	$\text{HNO}_2$	$1 \times 10^{10}$	Strong acid
$\text{NO}_2$ , nitrogen dioxide	$\text{N}_2\text{O}_3$	$2 \times 10^9$	Reacts with water to form nitrite
ROO, alkyl and alkoxy radicals	ROONO	$2 \times 10^9$	

The reaction products are not radicals

catalyzes the final step in the electron transport chain of mitochondrial respiration. It is inhibited by NO that competes with dioxygen for reversible binding to the catalytic binuclear  $\text{Cu}_B/\text{Heme}_{a3}$  binding site.

The main function of iNOS is the disabling of xenobiotics and tumor cells. NO released by macrophages and mast cells causes sufficient DNA damage in the attacked cells to induce apoptosis. The immunological potency of iNOS is further enhanced by the simultaneous release of substantial amounts of superoxide radicals, which cause oxidative damage.

The synthesis of prostaglandin and thromboxane hormones by cyclooxygenase enzymes is another important target of NO. With the exception of red blood cells, all mammalian cells release prostaglandins, which have an important role in inflammatory response, formation of blood clots, regulation of blood pressure, and muscle contraction.

## Main Reaction Pathways for NO

Biological tissues provide many reaction pathways for the NO radical. It may react with ubiquitous oxygen to the unstable dinitrogen trioxide, which rapidly hydrolyzes to nitrite

The overall reaction has second-order dependence on the NO concentration. In water, the modest rate constant of  $\sim 3 \times 10^6 \text{ mol}^{-2} \text{s}^{-1}$  makes this pathway negligible at normal physiological levels of oxygen and NO (below  $1 \mu\text{mol l}^{-1}$ ). However, this reaction may be accelerated by orders of magnitude by the presence of a hydrophobic lipid compartment. The local NO concentration is increased 10-fold because the uncharged NO molecule preferentially partitions into the nonpolar compartment.

NO reacts very rapidly with other free radicals like superoxide, ethyl alcohol radicals, or organic peroxy radicals (Table 3). Physiological antioxidant defenses keep levels of such free radicals very low under normal conditions, but superoxide levels, in particular, can be dangerously increased after ischemia, acidosis, sepsis, or septic shock. The reaction leads to the formation of the noxious oxidant peroxynitrite:

Although not a free radical itself, peroxynitrite is strongly oxidizing and capable of nitrosating proteins. It also disrupts [Zn-4S] clusters as they exist in functional NOS dimers, for example. Additionally, with  $\text{pK}_a = 6.8$  at  $37^\circ\text{C}$ , a sizable fraction of peroxynitrite will be protonated to  $\text{ONOOH}$ , which is known to decompose via an uncertain mechanism yielding highly reactive OH radicals.

**Table 4** Nitric oxide and its physiologically relevant metabolites

Species	Name	Gibbs energy of formation (kJ mol <sup>-1</sup> )
NO	Nitric oxide radical	102
NO <sup>+</sup>	Nitrosyl cation	219
NO <sub>2</sub>	Nitrogen dioxide radical	63
NO <sub>2</sub> <sup>-</sup>	Nitrite	-32.2
NO <sub>3</sub>	Nitrogen trioxide radical	131
NO <sub>3</sub> <sup>-</sup>	Nitrate	-108.7
N <sub>2</sub> O	Dinitrogen monoxide	113.6
ONOO <sup>-</sup>	Peroxynitrite	42

In biological systems, the presence of NO may affect proteins via nitration, nitrosation, or nitrosylation. Nitration involves the addition of NO<sub>2</sub><sup>+</sup>. Although NO itself is not an effective nitrating agent, its metabolites like peroxynitrite or the NO<sub>2</sub> radical may transform tyrosine residues into nitrotyrosine (Table 4).

The formation of this nitrated residue is dramatically increased under pathological conditions, and tyrosine nitration is used as a diagnostic marker for the simultaneous release of reactive oxygen and nitrogen species. The tyrosine nitration can strongly affect the function of the parent protein as it inhibits the tyrosine phosphorylation. The latter is an important mechanism of enzymatic regulation. Nitration by NO<sub>2</sub> radicals may transform amines into *N*-nitrosamines. Nitrosation involves the addition of an equivalent NO<sup>+</sup>. Sulfhydryl groups or cysteine residues are the main targets for nitrosative transformation to *S*-nitrosothiols (RSNO) in a slow and reversible reaction. In the presence of an electron acceptor, e.g., a transition metal ion, the reaction proceeds as

The RSNO groups are rather unstable and may release NO under ultraviolet light or in the presence of trace metal ions like monovalent Cu<sup>+</sup>. The nitrosyl cation NO<sup>+</sup> is a potent nitrosating agent also, but cannot exist under aqueous physiological conditions. Finally, NO may form nitrosyl complexes by binding to catalytic or structural metal sites in proteins. This liganding often competes with small ligands like dioxygen or carbonmonoxide. Fast and reversible binding performs a crucial regulatory role in vascular relaxation (heme of guanylate cyclase) or mitochondrial respiration (the dinuclear Cu<sub>B</sub>/Heme<sub>a3</sub> center of cytochrome C oxidase). However, in most other proteins the binding of NO to iron is inhibitory as in cytochrome P<sub>450</sub>, or structurally disruptive as in aconitases.

NO easily binds to transition metal complexes, in particular iron(II) and iron(III) complexes. In many cases, the binding of NO is sufficiently strong to displace other ligands and rearrange the complex. The disruption of enzymatic [Fe-S] clusters ultimately leads to the formation of paramagnetic dinitrosyl-iron complexes (DNICs) of the form (RS)<sub>2</sub>Fe<sup>2+</sup>(NO)<sub>2</sub>. NO also disrupts the structure of noniron metal centers like the [Zn-S] clusters in zinc finger proteins, thereby disabling a class of proteins involved in reparation of oxidative DNA damage. In the vascular system, hemoglobin (Hb) in the erythrocytes is a very efficient scavenger of NO. In oxygenated blood, 99% of the hemoglobin carries a dioxygen ligand and reacts rapidly and irreversibly with NO to methemoglobin (metHb) and nitrate. In the absence of a dioxygen ligand, NO binds rapidly but reversibly to form a stable mononitrosyl-iron complex with the heme. These reactions significantly reduce the NO concentrations in the muscle tissue surrounding the blood vessel, where NO acts as a signaling molecule for the activation of cGMP synthesis by the guanylate cyclase enzyme.

## Nitric Oxide in Clinical Pathology

Many hypertensive disorders reflect insufficient NO concentrations in the vascular system and are clinically treated by supplementation of NO. Pharmacological NO donors are effective against hypertension and angina pectoris, and pulmonary hypertension may be treated by low NO dosages in inhaled air. Macrophages kill bacteria and tumor cells by releasing large quantities NO from iNOS. However, extreme conditions of septic shock, sepsis, or cytokines may stimulate an excessive release of NO and cause an acute and profound drop in blood pressure (hypotension). Typical cases are induced by the endotoxins released after bacterial infections of abdominal traumas, by acute tissue rejection after organ transplantation or transfusion, or by chemotherapeutic treatment of neoplasias. Low-level inflammatory diseases like colitis, pancreatitis, and arthritis are associated with chronic overexpression of iNOS and can be treated by administration of specific iNOS inhibitors. On longer time-scales of years or decades, the proper function of eNOS is clearly correlated with good vascular function and low risk of hypertension, atherosclerosis, thrombosis, and stenosis. Cerebral NO production has been implicated in the brain damage caused by a temporary insufficiency of the oxygen supply (hypoxia-ischemia). Upon reoxygenation, the reactivation of the respiratory chain causes a massive release of superoxide radicals, which react with endogenous NO to form the harmful peroxynitrite. This reactive metabolite causes

subsequent oxidative and nitrosative damage to cerebral tissues. The formation of peroxynitrite may be reduced by supplementation of NOS inhibitors.

## Modulation of NO Levels *In Vivo*

Systemic NO levels in living animals may be raised in various ways: gaseous NO can be applied to exposed body surfaces like skin and lung tissue, and finds clinical application in accelerated healing of skin lesions and for treatment of pulmonary hypertension in newborn babies. Internal tissues can be reached with pharmaceutical NO donors like nitroglycerin, isoamyl nitrite, or NONO-ates that release NO in a controlled way. Paramagnetic DNICs with thiolate ligands  $(RS)_2Fe^{2+}(NO)_2$  decompose by a slow and reversible release of NO and a nitrosothiol:

At higher concentrations, nitrosothiols themselves may act as a donor via a metal-catalyzed formation of disulfide bonds:

Nitrosothiols are difficult to control as donors, since the release of NO is catalyzed by traces of free metal ions, in particular copper(I)  $Cu^+$ . The endogenous synthesis of NO may be enhanced by activating existing nitric oxide synthases with supplementation of co-factors like tetrahydrobiopterin, with folic acid or vitamin C, or by phosphorylation of certain serine groups of the enzyme. Alternatively, the expression of NOS enzyme in tissues or cell cultures may be artificially enhanced by gene therapy, i.e., genetic transfection with viral vectors. Finally, under favorable conditions NO levels may be increased by blocking the

main reaction channel for NO: removing superoxide radicals may dramatically enhance NO levels in animal tissues and facilitate the detection of NO.

Indiscriminate inhibition of all NOS isoforms is achieved by imidazole, *N*-methyl-L-arginine, L-nitro-arginine methyl ester, or by certain small proteins like PIN. Isoform-specific inhibition has only been achieved for iNOS, with inhibitors like aminoguanidine, aminoethyl-isothiourea, L-*N*-6-lysine or 1400W. In particular, the search for an effective and selective nNOS inhibitor has remained fruitless.

## Methods of NO Detection in Biological Systems

NO has an unusually long lifetime of the order of hours in oxygenated water at room temperature. However, in biological systems, scavengers like hemoglobin or superoxide may shorten this lifetime by orders of magnitude and make it very difficult to detect and quantify NO *in vivo* or *in vitro* directly. Thus, we can classify the detection techniques into three classes. The first class studies the presence of NO indirectly via its effect on the systemic response of a fully functional organism or tissue section. The second class detects reaction products or metabolites of NO. The third class involves direct detection of NO itself (Table 5).

### Detection via Systemic Response

**Vasorelaxation in vessel rings** NO may be detected through observation of vasorelaxation if the concentration exceeds the activation threshold of the guanylate cyclase enzyme. Quantification of NO is not possible and a vasoreactive response is also caused by impostors like Endothelium Derived Hyperpolarizing

**Table 5** Methods for the detection of nitric oxide in biological samples

Method	Material	Detection limit
Vasorelaxation in extracted tissues	Vessel rings ( <i>ex vivo</i> )	Nanomolar
Vasodilation	<i>In vivo</i> (human)	Nanomolar
Inhibition of platelet adhesion	Cultured cells	Nanomolar
Spectrophotometric with Griess reaction	Aqueous (urine, cerebrospinal fluid, plasma, cell culture medium)	Micromolar
Arginine to citrulline conversion	Aqueous, tissue	Nanomolar
Cyclic GMP	Aqueous, tissue	Nanomolar
Protein nitrosylation	Aqueous, tissue	Nanomolar
Histochemistry	Tissue (including imaging)	NA
Hemoglobin oxidation	Aqueous	Nanomolar
Fluorimetric	Aqueous, cultured cells (including imaging), tissue (including imaging)	Nanomolar
Chemiluminescence (gas phase)	Exhaled air, aqueous	Nanomolar
Chemiluminescence (liquid phase)	Tissue, aqueous	Picomolar
Electrochemical	Aqueous, <i>in vivo</i> (including humans), cultured cells	Nanomolar
Resistive NO sensors	Gas phase	10 ppm
Electron spin trapping	Aqueous, tissue, <i>in vivo</i> (animal)	Micromolar

NA, not applicable.

Factor, or substances that raise intracellular calcium levels and thereby artificially activate the constitutive NOS isoforms. The method may be applied to veins extracted from patients and laboratory animals but is impractical for diagnostic clinical use.

***In vivo* vasodilation** Two methods observe the release of NO by the endothelium by measuring changes in blood flow in humans. In flow-mediated dilatation, the diameter of the brachial artery is measured with ultrasound. The vasodilation is induced by the increase of arterial shear stress after the release of an inflatable cuff around the arm. Plethysmography measures the blood flow via the volume changes of the forearm after venous occlusion. Quantification of NO is not possible in either method and the diagnostic value is limited as individuals show considerable variations in systemic response.

**Inhibition of platelet adhesion** NO is a potent inhibitor of the aggregation of blood platelets, and the deceleration of the kinetics of platelet aggregation can be used as a qualitative but sensitive indicator for the presence of NO.

### Indirect Detection of NO

**Spectrophotometry with Griess reaction** One of the most widely used methods for NO detection is the spectrophotometric determination of the stable oxidation products of NO, in particular nitrite ( $\text{NO}_2^-$ ) and nitrate ( $\text{NO}_3^-$ ).  $\text{NO}_2^-$  is determined by the Griess coloring reaction and monitored via optical absorption spectroscopy at a wavelength of 540 nm.

**Arginine to citrulline conversion** The mammalian enzymes arginase and NOS both transform arginine into citrulline (see Figure 1). Still, the contribution of NOS to the arginine consumption may be unambiguously quantified via site-specific isotopic labeling of the arginine. The labeling site is chosen such that the label is removed from the citrulline if processed via the arginase pathway, but retained if the substrate is consumed by NOS. The isotopic labels may be unstable like  $^3\text{H}$  and  $^{14}\text{C}$  or stable like  $^{15}\text{N}$ . The citrulline yield may be quantified via column separation or liquid chromatography in combination with mass spectrometry. Alternative methods measure the radioactivity of the label using liquid scintillation counters. Radioactive isotopes have excellent detection sensitivity against a background of negligible natural abundance but require specialized and expensive lab facilities. In contrast, stable isotopes like  $^{15}\text{N}$  are simple and safe to use but suffer from high natural background levels.

**Levels of cGMP and activation of guanylate cyclase** NO regulates the activity of the cytosolic enzyme guanylate cyclase. This heterodimeric heme enzyme converts GTP into cGMP and pyrophosphate. The enzymatic yields of guanylate cyclase may be determined via isotopic labeling of the substrate. Quantification of the NO levels is not possible because the regulation of guanylate cyclase is not fully understood and because the activity of guanylate cyclase is affected by other compounds like C-type natriuretic peptide. Levels of cGMP may be determined in human body liquids like plasma or urine.

**Nitration or nitrosation of proteins** NO metabolites like  $\text{ONOO}^-$  or the  $\text{NO}_2$  radical can nitrate proteins by transforming tyrosine residues into characteristic nitrotyrosine groups. The degree of protein nitration can be determined with chromatographic and immunological techniques in tissue, plasma, and urine, and may serve as an indirect measure for the precursor molecule NO. The susceptibility for nitration varies with protein and requires the presence of other reactive oxygen species as NO itself is not a nitrating agent. Protein nitration is an accumulating process, as nitrotyrosine groups continue to be formed as long as reactive NO metabolites are released. Sulfhydryl groups or cysteine residues may be nitrosated reversibly to S-nitrosothiols. The latter are rather unstable and may be detected via their slow metal-catalyzed release of NO, or by biotinylation and subsequent gas chromatography-mass spectrometry.

**Histochemistry** Several NADPH consuming enzymes including NOS show an activity similar to NADPH diaphorase. The latter uses NADPH to convert soluble tetrazolium salts into insoluble visible formazan. Nitro blue tetrazolium is a widely used blue stain for NADPH diaphorase activity, and it has been observed that staining correlates well with NOS activity. The NOS contribution to the staining cannot be quantified, as several enzymes show diaphorase activity.

### Direct Detection of NO

**Hemoglobin oxidation** NO reacts rapidly with reduced oxyhemoglobin,  $\text{HbFe}^{2+}\text{O}_2$ , to form methemoglobin ( $\text{HbFe}^{3+}$ ) and  $\text{NO}_3^-$ . The oxidation state of the heme group is easily followed spectrometrically at wavelengths near 400 nm. A variation of this technique is the use of the iron-containing enzyme horseradish peroxidase or oxymyoglobin instead of oxyhemoglobin.

**Fluorimetric trapping** Fluorimetric trapping is based on the reaction of a suitable trap-molecule

with NO or nitrite with a fluorescent reaction product called 'adduct'. Suitable traps are those where the adduct has fluorescent properties very distinct from those of the original trap. Easiest to use are nonfluorescent traps with fluorescent adducts like 2,3-diaminonaphthalene, which can detect  $\text{NO}_2^-$  in cell culture medium, plasma, and urine but not in tissues. Fluorescent dyes like dihydrorhodamine and dichlorofluorescein (DCF) change their fluorescence spectra upon reaction with NO, but similar spectral changes are caused by reactive oxygen or nitrogen species other than NO. This lack of specificity makes these traps unsuitable for unambiguous determination of NO. The fluorescent trap diaminofluorescein (DAF) has been widely used in cultured cells, flow cytometry, and NO imaging. The diacetate variant DAF-2-DA is electrically neutral, cell permeable, and accumulates in viable cells as cellular esterases hydrolyze the acetate groups into negatively charged acid residues. DAF is not specific as it may react with NO imposters like peroxynitrite,  $\text{N}_2\text{O}_3$ , and even ascorbic acid. Additionally, catecholamines and certain antioxidants interfere in the reaction with NO. Good specificity for NO is reported for cheletropic nitric oxide traps (FNOCT). This red fluorescent trap reacts with NO to a blue-fluorescent adduct and has been used to determine NO levels in cell cultures and tissues (Figure 5).

**Chemiluminescence in the gas phase** In the gas phase, ozone will react with NO to form electronically excited nitrogen dioxide radicals. Upon relaxation some emit visible light, which may be easily

and sensitively detected. This method has been used to detect NO in exhaled air in chronic renal or hemodialytic patients. In aqueous media, dissolved NO may be released into the gaseous phase by bubbling with an inert gas like nitrogen or argon. NO metabolites like nitrate, nitrite, or nitrosothiols can be quantified by reductive reconversion into NO. For liquid samples, the sensitivity for NO detection has been reported at  $\sim 100 \text{ pmol l}^{-1}$ . The method can only be used on gaseous or aqueous samples like cell culture media, plasma, and urine, but NO levels inside cells or tissues remain inaccessible.

**Chemiluminescence in the liquid phase** Chemiluminescent markers may be used to detect radical molecules like superoxide or NO. Luminol in particular reacts with NO to give a metastable intermediate, which relaxes by light emission at 427 nm. The method is sensitive, but unspecific, as the same emission is also observed with a range of other reactive oxygen and nitrogen species. In addition, the method cannot be used with optically dense samples like tissue.

**Electrochemical detection with sensing electrodes** Electrodes can detect NO in the liquid phase via the redox couple:

The electrical current generated at the anode is directly proportional to the NO concentration in solution. Electrochemical electrodes have been used to detect NO released by cultured cells or isolated

**Figure 5** The mechanism of NO detection by cheletropic traps. Cellular esterases transform the membrane penetrating FNOCT ester into an acid that accumulates inside the cell. The red-fluorescent FNOCT trap reacts with NO to an unstable nonfluorescent nitroxide radical. The latter is hydroxylated to give a stable blue-fluorescent adduct.

tissues and even directly in the human vasculature. Electrochemical detection determines the NO concentrations and thus the NO bioavailability, not the actual NO production. The selectivity for NO may be greatly enhanced by modification of the electrode surface with polymeric ion exchangers. Spatial resolution is obtained with electrochemical micro-sensors where thin (5–10  $\mu\text{m}$ ) carbon fibers receive a surface cover of polymerized phthalocyanines or porphyrins and ion-selective Nafion layers. Concentration gradients of NO may be measured with oscillating microsensors. Interference from nitrite or catecholamines is problematic, the electrodes are difficult to handle, and the covering membranes are very sensitive to environmental influences and mechanical damage.

**Electron paramagnetic resonance (ESR)** Although NO is a paramagnetic radical with spin  $S=1/2$ , its degenerate ground state makes it impossible to detect directly with electron paramagnetic spin resonance spectroscopy. But its fairly long lifetime allows its capture and stabilization by diamagnetic spin trapping compounds. Certain iron complexes in particular have high affinity for NO ligands and form stable mono- or dinitrosyl-iron complexes, which are paramagnetic and may be quantified with ESR. This method is particularly valuable for NO detection in tissues.

## Introduction

Nitrogen is an essential element for all forms of life and is the structural component of amino acids from which animal and human tissues, enzymes, and many hormones are made. For plant growth, available (fixed) nitrogen is usually the limiting nutrient in natural systems. Nitrogen chemistry and overall cycling in the global environment are quite complex due to the number of oxidation states. Nitrogen itself has five valence electrons and can be found at oxidation states between  $-3$  and  $+5$ . Thus, numerous species can form from chemical, biochemical, geochemical, and biogeochemical processes. **Table 1** lists by oxidation state some of the most prevalent

nitrogen species (and important chemical data) that exist in the global environment.

## Global Nitrogen Distribution

The global distribution of nitrogen (both reservoirs and fluxes) is shown in **Table 2**. The atmosphere is the principal nitrogen reservoir, with over 99% of the total in the form of  $\text{N}_2$ . Nitrogen in terrestrial systems occurs mainly as a constituent in soil organic matter, with litter and soil inorganic nitrogen accounting for the majority (97%). Biomass accounts for just fewer than 3%; of this, 95% occurs in plant tissue. Dinitrogen, in dissolved form ( $\text{N}_{2,\text{aq}}$ ), is the most abundant nitrogen form in the world's oceans. Nitrogen also occurs in both inorganic forms (e.g., nitrate, nitrite, ammonia, hydrazine, nitrous oxide, and nitrogen dioxide) and organic forms (e.g., amino acids, amines, and amides). Amino acids are minor but important constituents of dissolved organic

tissues and even directly in the human vasculature. Electrochemical detection determines the NO concentrations and thus the NO bioavailability, not the actual NO production. The selectivity for NO may be greatly enhanced by modification of the electrode surface with polymeric ion exchangers. Spatial resolution is obtained with electrochemical micro-sensors where thin (5–10  $\mu\text{m}$ ) carbon fibers receive a surface cover of polymerized phthalocyanines or porphyrins and ion-selective Nafion layers. Concentration gradients of NO may be measured with oscillating microsensors. Interference from nitrite or catecholamines is problematic, the electrodes are difficult to handle, and the covering membranes are very sensitive to environmental influences and mechanical damage.

**Electron paramagnetic resonance (ESR)** Although NO is a paramagnetic radical with spin  $S=1/2$ , its degenerate ground state makes it impossible to detect directly with electron paramagnetic spin resonance spectroscopy. But its fairly long lifetime allows its capture and stabilization by diamagnetic spin trapping compounds. Certain iron complexes in particular have high affinity for NO ligands and form stable mono- or dinitrosyl-iron complexes, which are paramagnetic and may be quantified with ESR. This method is particularly valuable for NO detection in tissues.

N <sub>2</sub> O(g)	+1	-89	82	104
N <sub>2(g)</sub>	0	-196	0	0
NH <sub>3(g)</sub>	-3	-33	-46	-16.5
NH <sub>4</sub> <sup>+</sup> <sub>(aq)</sub>	-3		-72	-79
NH <sub>4</sub> Cl <sub>(s)</sub>	-3		-201	-203
CH <sub>3</sub> NH <sub>2(g)</sub>	-3		-28	28

**Table 2** The major global reservoirs and fluxes of nitrogen

Reservoir	10 <sup>15</sup> g N
Lithosphere	190 000 000
Atmosphere	3 900 000
Oceanic	23 000
Terrestrial	500
Flux	10 <sup>15</sup> g N year <sup>-1</sup>
Dry and wet deposition (terrestrial + oceanic)	0.160–0.450
Denitrification (terrestrial)	0.043–0.390
Denitrification (oceanic)	0–0.330
Biological nitrogen fixation (terrestrial)	0.044–0.200
Biological nitrogen fixation (oceanic)	0.001–0.130
River runoff (terrestrial → oceanic)	0.013–0.040

nitrogen (DON), which are readily used by bacteria and some phytoplankton. Studies involving DON fractions isolated from seawater by solid-phase extraction and ultrafiltration, for example, have shown that D-enantiomers of some amino acids are present in significant amounts. In general, the organic fraction is not well characterized and estimated from knowledge of the carbon content and C:N ratios. Nitrous oxide (N<sub>2</sub>O) emissions arise from fertilized arable land, animal excreta, postclearing effects on soil emissions, fossil fuel, and industrial sources. N<sub>2</sub>O from animal excreta, in particular, form a significant (~50%) source of total emissions. Additional N<sub>2</sub>O is thought to arise in tropical soils through the process of denitrification, and currently, biogeochemists are devoting a large research effort to understand the true importance of this source of nitrogen.

## Activity Diagrams

Redox potential-pH diagrams are very useful as a way to visualize and summarize the aqueous speciation of redox-sensitive elements. pH is the negative base-10 logarithm of proton activity in aqueous solution,  $-\log a_{\text{H}^+}$ . Many variables are commonly employed to express redox conditions: Eh (electrode potential of a half-cell reaction with reference to standard hydrogen electrode),  $pe$  (electron activity in aqueous solution),  $f_{\text{O}_2}$  (fugacity of oxygen), and  $f_{\text{H}_2}$  (fugacity of hydrogen). They are all more or less useful depending on a specific problem, or an approach to measurements or calculations, and can be readily converted from one to the other given the appropriate conversion factors. Fugacity of hydrogen,  $f_{\text{H}_2}$ , is a convenient parameter because any redox reaction can be written to include hydrogen as a product or reactant. High values of  $\log f_{\text{H}_2}$  indicate reducing conditions whereas low  $\log f_{\text{H}_2}$  values indicate oxidizing conditions. An  $f_{\text{H}_2}$ -pH plot is a type of activity diagram that indicates both oxidation-reduction and acid-base conditions.

Figure 1 is an activity diagram for the N–O–H system at 25°C and 1 bar. The horizontal bold lines in the plot correspond to reducing (upper) and oxidizing (lower) boundaries in terms of  $\log f_{\text{H}_2}$  where H<sub>2</sub>O is stable. The dissociation reaction of water is:

where, at equilibrium

$$\log K = \log f_{\text{H}_2} + \frac{1}{2} \log f_{\text{O}_2}$$

and

$$\log f_{\text{H}_2} = \log K - \frac{1}{2} \log f_{\text{O}_2}$$

The usual atmospheric O<sub>2</sub> defines the oxidizing boundary of water stability, and we may use 0.21 bar (or  $\log f_{\text{O}_2} = -0.68$ ) since oxygen makes up ~21% of the atmosphere by volume. Combining with the equilibrium constant of reaction [14] in Table 3, this corresponds to  $\log f_{\text{H}_2} = -41.21$ . The reducing boundary occurs at 1 bar H<sub>2(g)</sub> since the pressure of hydrogen gas in surface environments cannot exceed the atmospheric pressure, and this sets the upper boundary at  $\log f_{\text{H}_2} = 0$ .

For the vertical line separating NH<sub>4</sub><sup>+</sup> and NH<sub>3(aq)</sub>,

$$\log K = -\text{pH} + \log a_{\text{NH}_3} - \log a_{\text{NH}_4^+}$$

If we consider  $a_{\text{NH}_3} = a_{\text{NH}_3^+}$ , the equation reduces to  $\text{pH} = -\log K$ , or  $\text{pH} = 9.24$ . So this line corresponds

**Figure 1** Plot of  $\log f_{\text{H}_2}$  versus pH at 25°C and 1 bar total pressure showing fields of relative predominance of aqueous nitrogen species.  $\log f_{\text{H}_2}$  values represent numerical indices of the oxidation state of the system. Each line has a matching chemical reaction as listed in **Table 3**. Bold horizontal lines establish the stability limits for water. Dashed lines define the area of dissolved nitrogen in equilibrium with an atmosphere containing 78%  $\text{N}_2$ .

to the pH where the activity of  $\text{NH}_4^+$  equals the activity of  $\text{NH}_3(\text{aq})$ . At  $\text{pH} > 9.24$ , the ratio  $a_{\text{NH}_3}/a_{\text{NH}_4^+}$  is greater than 1; at any pH values left of this line, less than 1.

Consider next the redox couple between nitrite and ammonium ion,

This reaction includes both proton and hydrogen, and so the equilibrium constant expression gives:

$$\log K = \log a_{\text{NH}_4^+} - \log a_{\text{NO}_2^-} + 2\text{pH} - 3 \log f_{\text{H}_2}$$

Setting the activity of  $\text{NH}_4^+$  equal to the activity of  $\text{NO}_2^-$ , rearrangement gives  $\log f_{\text{H}_2}$  as a function of pH:

$$\log f_{\text{H}_2} = \frac{2}{3} \text{pH} - \frac{1}{3} \log K$$

This equation has a slope of 2/3 and its intercept can be evaluated from the  $\log K$  of reaction [6] in **Table 3**, and it is plotted in **Figure 1** as a line that separates the predominant areas for  $\text{NH}_4^+$  and  $\text{NO}_2^-$ . Using these methods, similar lines can be constructed for the other aqueous nitrogen species. The appropriate

reactions and their equilibrium constants are listed in **Table 3**. Also overlaid in the figure are dashed lines, derived from reactions [10] to [13], that illustrate the area of nitrogen,  $\text{N}_{2(\text{aq})}$ , dissolved in aqueous solutions in contact with the atmosphere having 78%  $\text{N}_2$ .

## Nitrogen Speciation

The activity diagram such as **Figure 1** is constructed for the N– $\text{H}_2\text{O}$  system, and in it, fields separated by lines essentially map out the predominant nitrogen species over ranges of pH and redox potential in  $f_{\text{H}_2}$ . Each field defines the redox and pH conditions in which a particular nitrogen species predominates. This does not mean that other species are unstable or nonexistent, but they are minor constituents. Moreover, the figure is drawn to show equilibrium relations tied to the equilibrium constants at a given temperature and pressure for a set of nitrogen reactions (**Table 3**). Although natural environments often do not attain equilibrium in reasonable time, an equilibrium diagram is useful to provide a backdrop against which compounds out-of-equilibrium are revealed. Such diagram can then be used as a ‘biogeochemical map’ to illustrate nitrogen speciation and a variety of biological and geochemical transformations

(see the section ‘Biogeochemical cycling processes’ below).

For example, under oxidizing conditions as in river runoffs and surface waters, we would expect to find  $\text{NO}_3^-$ . By contrast,  $\text{NH}_4^+$  or  $\text{NH}_3$  predominates in

reducing conditions; therefore, the occurrence of  $\text{NH}_4^+$  or  $\text{NH}_3$  in oxidizing environments represents species out of equilibrium, and this oxidation of  $\text{NH}_4^+$  or  $\text{NH}_3$  to  $\text{NO}_3^-$  is thermodynamically favorable. Where this oxidation reaction is hindered by slow reaction rate, microorganisms can tap into this nitrification reaction for energy (see below). The field of dissolved nitrogen  $\text{N}_{2(\text{aq})}$  occupies wide ranges of pH and redox conditions and represents many aqueous environments in contact with the atmosphere. Because  $\text{N}_{2(\text{aq})}$  is the predominant species, as shown in **Figure 1**, the conversion of  $\text{N}_2$  to other nitrogen compounds (as in biological fixation) requires the input of energy. This process is carried out by a wide variety of bacteria and algae via enzyme catalysis or photosynthesis.

**Table 3** Equilibrium constants at 25°C and 1 bar for nitrogen reactions and the dissociation reaction of water

Reaction	$\log K^a$
1 $\text{HNO}_{3(\text{aq})} \leftrightarrow \text{NO}_3^- + \text{H}^+$	1.303
2 $\text{NH}_4^+ \leftrightarrow \text{NH}_{3(\text{aq})} + \text{H}^+$	-9.241

## Biogeochemical Cycling Processes

A schematic of the biological nitrogen transformations of nitrogen species is shown in **Figure 2** with the main processes listed below. All of these processes are mediated by various types of microorganisms with some processes being energy producing and others occurring symbiotically with other organisms.

### Nitrogen Fixation

Nitrogen fixation is the process by which nitrogen is taken from its molecular form ( $\text{N}_2$ ) in the atmosphere and converted into nitrogen compounds useful for other biochemical processes. Fixation can occur through atmospheric (lightning), industrial, or biological processes. Biological nitrogen fixation can be represented by the following reaction, in which the enzyme-catalyzed reduction of  $\text{N}_2$  to  $\text{NH}_3$ ,  $\text{NH}_4^+$ , or

**Figure 2** Schematic representation of the biological transformations of nitrogen species.

organic nitrogen occurs:

This process is performed by a variety of prokaryotes, both symbiotic and free living, using an enzyme complex termed nitrogenase that is composed of two separate protein components (dinitrogenase reductase and dinitrogenase). Dinitrogenase reductase donates two high potential electrons at a time to dinitrogenase and contains an Fe–S center that holds the electrons before donation. Dinitrogenase then catalyzes the reduction of  $\text{N}_2$ . Once nitrogen has been fixed, it can be oxidized to  $\text{NO}_2^-/\text{NO}_3^-$  or assimilated by organisms.

### Ammonia Assimilation

Ammonia assimilation is the process in which the fixed  $\text{NH}_3$  or  $\text{NH}_4^+$  is transformed to the organic form through assimilation by organisms to become part of their biomass. This process is of great importance for those organisms that can directly utilize nitrogen as  $\text{NH}_3$  or  $\text{NH}_4^+$ .

### Nitrification

This process describes the oxidation of  $\text{NH}_3$  or  $\text{NH}_4^+$  to  $\text{NO}_2^-$  or  $\text{NO}_3^-$  by organisms. Nitrification occurs in two energy-producing steps: (1) oxidation of ammonia to nitrite and (2) the subsequent oxidation of nitrite to nitrate. The following general reactions represent the two nitrification steps:

This process is used primarily by a group of aerobic chemotrophs called the nitrifiers. While some low levels of heterotrophic nitrification do occur, rates are low and quantities of nitrate produced are relatively small compared to those by the chemotrophs. The oxidation of ammonia into nitrite is done by *Nitrosomonas* species with the second step performed by *Nitrobacter* species.

### Assimilatory Nitrate Reduction

In the global environment, nitrogen in the form nitrate or nitrite is assimilated (immobilized) into biomass in the form of  $\text{NH}_3$ . This reduction is catalyzed by two assimilatory enzymes (nitrite reductase and nitrate reductase) and can be carried out by plants, fungi, and prokaryotes. This process is likely to dominate when reduced nitrogen is in low supply (e.g., during aerobic conditions).

**Table 4** Selected methods for the determination of nitrogen species in waters

Species	Method and description <sup>a</sup>
Nitrate and nitrite	<p>Direct determination: In electrochemical procedures, ion-selective electrodes are used.</p> <p>In spectroscopic methods, ultraviolet absorbance can quantify nitrate and nitrite; nitrite may first require separation</p> <p>Indirect determination: Approach that is based on reduction of nitrate to nitrite (e.g., by cadmium) with nitrite measured directly or via derivatization</p> <p>Chromatography: Ions are separated using ion chromatography, ion-exchange, ion-exclusion, and ion-interaction techniques</p> <p>Flow injection analysis (FIA): This versatile method can be coupled with various modes of detection (e.g., spectrophotometric, luminescence, electrochemical)</p>
Ammonia	<p>Titrimetric determination: Volumetric titration (e.g., acid–base) is used to determine the amount of ammonia</p> <p>Indophenol blue colorimetry: Ammonia is reacted with phenolic agents to form blue indophenol dyes (absorbs at a wavelength range of 630–720 nm)</p> <p>Ammonia-selective electrode: These electrodes are electrochemical cells in which a potentiometric signal is correlated with the concentration of ammonia</p> <p>Chromatographic techniques: Methods that involve the separation of components in a mixture; e.g., gas chromatography, liquid chromatography, and ion chromatography</p> <p>FIA</p>
Organic nitrogen	<p>Kjeldahl method: Organic nitrogen is converted to ammonia using metals such as mercury and selenium as catalysts</p> <p>Photochemical oxidation: This method involves the use of ultraviolet radiation to decompose organic matter, during which organic nitrogen is oxidized to nitrate</p> <p>High-temperature combustion: During pyrolysis at 900–1100°C, organic nitrogen is transformed into NO, which can be quantified by chemiluminescence, or be further reduced to <math>\text{N}_2</math> and detected by thermal conductivity</p> <p>Koroleff method: Under strongly alkaline medium, total nitrogen is oxidized to nitrate using potassium peroxodisulfate</p> <p>FIA</p>

## Denitrification

Denitrification (often referred to as dissimilatory nitrate reduction) is the microbial reduction of  $\text{NO}_3^-$  to  $\text{N}_2$ . The reaction steps require an organic carbon as electron donor ( $\text{CH}_2\text{O}$  generically used) and are shown below:

Many denitrifying bacteria consume organic matter while utilizing  $\text{NO}_3^-$  as their electron acceptor. Thus, denitrification can readily occur in the presence of organic matter, in soils devoid of oxygen, and with the help of denitrifying bacteria. These denitrifiers are represented by many diverse species: both the Gram-positive and Gram-negative bacteria, as well as archaea; some are thermophilic and others are halophilic.

## Ammonification

This process involves the breakdown of organic nitrogen compounds (from soil or aquatic organic compounds) into  $\text{NH}_3$  or  $\text{NH}_4^+$ . Heterotrophic bacteria are principally responsible for the process of ammonification, utilizing organic nitrogen compounds and leaving behind  $\text{NH}_3$  and  $\text{NH}_4^+$ . These nitrogen species can then be recycled back into the biosphere.

## Nitrogen Determination

A variety of methods has been described for the determination of nitrogen species (Table 4) but not all are routinely used. The cadmium reduction method is widely used in both batch and automated (continuous flow) spectrophotometric methods. In this procedure, nitrate is reduced to nitrite, which is then determined by diazotization with sulfanilamide and coupling with *N*-(1-naphthyl)ethylenediamine dihydrochloride (NED) to form an intensely pink-colored azo dye. This chemistry can be incorporated in a flow injection manifold to allow rapid, automated, *in situ* determinations in a robust and portable manner. Other common techniques for nitrogen determination are the nitrate ion-selective electrode and ion chromatography.

## Global Outlook

As discussed, the global nitrogen cycle comprises many important chemical, biochemical, geochemical, and biogeochemical processes. Nitrogen is also tightly coupled with other elements (carbon, phosphorus, sulfur, and trace metals) and understanding these relationships will help in determining the role of living matter in biogeochemical cycles. The effect of human activity on the global nitrogen cycle is also of interest. The realization that nitrogen is commonly a limiting nutrient in plant growth has led to the invention and large-scale usage of nitrogen fertilizers, which in turn accounts for more than half of the human perturbation to the global nitrogen cycle. In addition, the widespread use of fossil fuels has led to the increased production of nitrogen oxides, which ultimately contribute to photochemical smog and acid precipitation. However, it is difficult to assess the true impact of these inputs given the extent and magnitude of natural fluxes. Only through continued study of the important processes that occur in the nitrogen cycle, will we truly understand the relative impacts.

## Introduction

Nitrosamines is a general term used to designate a vast group of *N*-nitroso compounds (NOCs), bearing a common functional  $>\text{N}-\text{N}=\text{O}$  group. The NOCs can be divided into two classes: *N*-nitrosamines and *N*-nitrosamides and related compounds. *N*-Nitrosamines are *N*-nitroso derivatives of secondary amines (Figure 1A); *N*-nitrosamides and its related compounds are those of substituted ureas, amides, carbamates, guanidines, and similar compounds (Figure 1B).

The interest for this group of compounds increased since the evidence of their mutagenic and carcinogenic properties. Most NOCs induce cancer in laboratory animals and may be involved in the etiology of several human cancers. The wide range of human exposure sources (exogenous and endogenous) have led to the necessity of regulatory and legislative action and to the search of advanced and sensitive methods of analysis (see Table 1).

Among the vast group of compounds included under the term of NOC some are of special interest. That is the case of the simplest *N*-nitroso compound, *N*-nitrosodimethylamine (NDMA), or the so-called tobacco-specific nitrosamines (TSNAs), which are among the most abundant carcinogens identified in tobacco and its smoke. Seven TSNAs have been identified both in tobacco filler and tobacco smoke. They are nonvolatile and formed by nitrosation of nicotine and related tobacco alkaloid precursors with

nitrogen oxides. Some examples of the most representative NOCs are represented in Figure 1.

## Mutagenicity and Carcinogenicity of Nitrosamines

Experimental animal studies have established nitrosamines as a family of extremely potent carcinogens. Their cancer potencies are much higher than those of the trihalomethanes and it is for this reason that the International Agency for Research on Cancer (IARC) of the World Health Organization has focused great interest in this group of compounds.

Nitrosamines are not mutagenic *per se*, but if they are activated by liver enzymes such as cytochromes P50 (CYP2E1) and 2A6 (CYP2A6), they are able to react with DNA and the methylated DNA damage is then misrepaired resulting in modified transition of guanine–cytosine, adenine–thymine base pairs and finally in carcinogenicity. Many dialkyl nitrosamines are potent mutagens and carcinogens in rodents as well as powerful alkylating agents in humans.

Approximately 300 different *N*-nitrosamines can induce cancer in experimental animals. Some representative compounds of this class induce cancer in at least 40 different animal species, including higher primates. Experimental studies from animals can induce tumors in animals that resemble their human counterparts with respect to both morphological and biochemical properties. Nitrosamines are classified as suspect human carcinogens even though direct causal evidence is lacking. Literary data on the evaluation of carcinogenic hazard of nitroso compounds and in particular NDMA confirm their hazardous impact on humans due to chronic immunosuppression. Acute (short-term) exposure to NDMA may damage the liver in humans, with symptoms that include nausea, vomiting, headaches, and malaise. Chronic (long-term) exposure of humans to NDMA may cause liver damage and low platelet counts. Severe liver damage has been observed in animals. Animal studies have suggested that chronic ingestion and inhalation of NDMA may cause an increase in liver tumors and other types of tumors. EPA has classified NDMA as a Group B2, probable human carcinogen. Published data establish the total safety dose of NDMA at 0.1 mg per animal to determine NDMA safety levels in environment, i.e., atmospheric air and water reservoirs, at  $0.0001 \text{ mg m}^{-3}$  and  $0.0001 \text{ mg l}^{-1}$ , respectively, and to establish the total human safety level of NDMA at less than  $0.002 \text{ mg day}^{-1}$ .

Increasingly, extensive experimental and some epidemiological data suggest that humans are susceptible to carcinogenesis by *N*-nitroso compounds

and that the presence of these compounds in some foods or the exposition to certain occupational settings may be regarded as an etiological risk factor, including cancers of the esophagus, stomach, nasopharynx, urinary bladder, childhood leukemia, brain, and colon. Esophageal cancer represents one of the most common and lethal cancers around the world and extensive data have showed that nitrosamines are the only carcinogens capable of inducing tumors in the esophagus of experimental animals, especially with the rat, which are the most susceptible species.

Of the seven TSNAs identified as components of tobacco and tobacco smoke, *N*-nitrosonornicotine (NNN), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) are considered the most carcinogenic. NNK and its primary metabolite, NNAL, are expected to be particularly important in the induction of adenocarcinoma, which is now the leading lung cancer type in the United States.

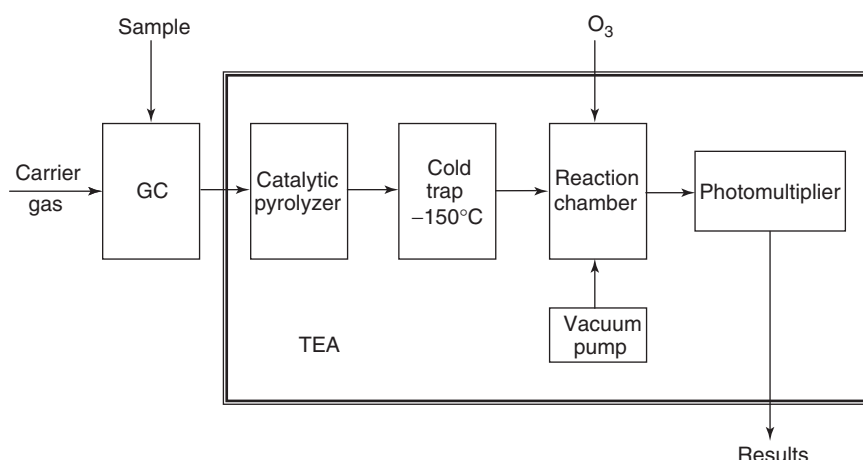

## Quantitative Analysis

Since the carcinogenic properties of nitrosamines were evidenced, the identification of these compounds in a wide range of foodstuffs represented a primary objective for many researchers. The analytical techniques initially applied to this purpose, such as thin-layer chromatography, gas chromatography (GC) with flame ionization or Hall detection, spectrophotometry, or polarography, lacked the necessary specificity and/or sensitivity to give reliable results and reports of false positive results were not uncommon. The development of more selective methodologies was required.

The only detection method that is recognized as specific for nitrosamines is the thermal energy analyser (TEA). This technique, combined with GC separation, has become the most commonly used detection method for volatile NOCs because of its specificity, speed, and accuracy. A functioning scheme is represented in Figure 2. The GC eluent is introduced into a catalytic pyrolyzer where the catalytic cleavage of the *N*-nitroso bond is produced, releasing the nitrosyl radical ( $\text{NO}^\bullet$ ):

The reaction products are swept through a cold trap at  $-150^\circ\text{C}$  to remove potentially interfering products. In a reaction chamber, the nitrosyl radical is oxidized by ozone to give electronically excited nitrogen dioxide that rapidly decays back to the

**Figure 2** Schematic representation of the thermal energy analyzer (TEA).

ground state emitting red light at 600 nm:

Measurement of this radiation by a sensitive photomultiplier tube allows an accurate and specific determination of the NOCs present.

There are, however, a large number of polar nitroso compounds not generally amenable to direct analysis by GC, either because of their low volatility or their thermal instability. The determination of these nonvolatile NOCs was initially hampered by the incompatibility of the TEA with reversed-phase liquid chromatography (LC), because the polar mobile phase affects the stability of the detection signal. Interest in the analysis of nonvolatile *N*-nitrosamines has, however, been renewed due to the recent development of several new reversed-phase liquid chromatography (LC) interfaces to TEA or chemiluminescence detection. An efficient photolytic interface between LC and TEA detector has been developed. The chromatographic eluent is introduced into a glass coil irradiated with ultraviolet (UV) light with a purge stream of helium. Nitrogen oxide produced by photolysis is carried by helium through three cold traps to the reaction chamber of the TEA. This interface allows an efficient link between LC and TEA, providing good selectivity and sensitivity for nonvolatile *N*-nitrosamines, but it is not commercially available. An improved procedure using LC in combination with postcolumn photolysis has been developed. In this method, the LC effluent is transferred to a Teflon tube in a reaction chamber that is irradiated by a high-intensity discharge lamp emitting at 254 nm. The NOCs are cleaved by the UV radiation and the nitrosyl radicals formed are oxidized to

$\text{NO}_2$  radicals, which further react to give  $\text{N}_2\text{O}_3$  and  $\text{N}_2\text{O}_4$ . Both  $\text{N}_2\text{O}_3$  and  $\text{N}_2\text{O}_4$  are unstable in aqueous surroundings and will convert to nitrite. The effluent from the photohydrolysis coil is mixed with Griess reagent. The azo compound formed by reaction of nitrite with Griess reagent is measured spectrophotometrically at 546 nm.

A new application of a counter-flow gas diffusion cell (CFGDC)-based particle beam LC interface has been described for the LC-TEA analysis of nonvolatile *N*-nitrosodiethanolamine and *N*-nitroso-methyl-*p*-amino-2-ethylhexylbenzoate. The interface incorporates a thermospray vaporizer, desolvation chamber, and CFGDC to reduce the LC effluent to a dry aerosol and a single-stage momentum separator to form a particle beam of the nonvolatile analyte.

LC combined with postcolumn chemiluminescence detection has also been applied to the determination of trace *N*-nitrosamines in groundwater. The method combines solid-phase extraction (SPE) on to a mini-activated carbon column, followed by elution with acetone and concentration of the extracts by denitrosation and fluorogenic derivatization. Peroxyoxalate chemiluminescence detection was carried out by using bis(2-nitrophenyl) oxalate and hydrogen peroxide as chemiluminescent reagents. The method provides *N*-nitrosamines detection at picomole per liter levels.

Another strategy has been developed for the analysis of total NOCs, including the injection of the sample into boiling ethyl acetate containing HBr/HAc and further transference of the nitrosyl radicals formed into the reaction chamber of the TEA detector by a nitrogen stream; a scheme is represented in **Figure 3**. Only the total amount of nitrosamines can be determined since the method cannot distinguish between various nitrosamines.

The TEA has been the predominantly applied detection system for the analysis of NOCs, even though

**Figure 3** Schematic representation of quantitative determination of total NOCs.

this system is expensive and not available in most laboratories. For this reason there is the frequent use of GC–mass spectrometry (GC–MS) and LC–electrospray ionization (ESI)–MS. Thus, GC with tandem mass spectrometry in the chemical ionization mode (GC–CI–MS/MS) or GC with high-resolution mass spectrometry (GC–HRMS) have become the most common techniques currently used for analysis of low concentrations of NDMA. Recently, LC–MS/MS has been applied for the analysis of tobacco-specific *N*-nitrosamines in snuff or mainstream cigarette smoke, reporting detection limits ranging from 0.005 to 0.01 mg g<sup>-1</sup> and from 0.05 to 1.23 ng ml<sup>-1</sup> respectively. One of the main problems when using LC–MS/MS detection is signal suppression, or sometimes enhancement, caused by coeluting matrix components. To avoid these matrix effects, a thorough cleanup of the samples is often required. Alumina or silica gel column chromatography or SPE procedures with different sorbents (Oasis HLB) have been assayed.

*N*-Nitrosamines are directly determined as the free forms by GC–TEA. However, other GC- and LC-based methods have been referenced based on the application of derivatization reactions. Precolumn or postcolumn derivatization of the *N*-nitroso compounds very often provides unsatisfactory sensitivities. Better results can be obtained by previous denitrosation of the NOCs and subsequent detection of liberated secondary amines via derivatization. Denitrosation can be obtained by reaction with hydrobromic acid and the subsequent derivatization of the secondary amines formed by reaction with typical derivatization agents such as dansyl chloride or diethyl chlorothiophosphate.

The recovery of nitrosamines at ultratrace level requires the development of adequate preconcentration methods. Depending on the matrix to be analyzed different procedures have been used. Liquid–liquid extraction has widely been applied using different solvents such as dichloromethane, ethyl acetate, and buffer solution.

Supercritical fluid extraction (SFE) using supercritical carbon dioxide (SC–CO<sub>2</sub>) has been successfully used for isolation of volatile nitrosamines from different matrices such as tobacco and food products. This technique presents several advantages with respect to other extraction methods (e.g., mineral oil distillation or low-temperature vacuum distillation) currently used. Thus, SFE minimizes sample handling, provides fairly clean extracts, expedites sample preparation, and reduces the use of environmentally toxic solvents. Good results have also been obtained with the use of SPE in the analysis of food matrices combining extraction with Extrelut sorbent and purification with Florisil. This method is applicable for the analysis of a range of the most widely encountered volatile *N*-nitrosamines, including the poorly volatile NDBA, NDBzA, and *N*-nitroso-*N*-methylaniline in various food products. Active carbon is suitable for this preconcentration step due its low cost, versatility, and easy application.

A serious problem in NOC analysis is the risk of the formation of artifacts during storage, preparation, and analysis, due to the presence of relatively large amounts of precursors, and by the low concentration of NOCs, if present. Therefore, adequate measures have to be taken to prevent and detect the formation of artifacts. SPE methods are free of artifactual formation of *N*-nitrosamines, common when

a vacuum distillation procedure is used. In this procedure, during the distillation step, where nitrosamines precursors are present, there must be strict control.

## Human Exposure

*N*-Nitrosamines are widely distributed in various human environments. The concern was initially focused on their widespread occurrence in food and consumer products, as beer, meats cured with nitrite, smoked fish, tobacco and tobacco smoke, rubber products including baby bottle nipples and pacifiers, cosmetics, drug formulations, or herbicides formulations. Much data of their occurrence have been obtained by inadequate analytical methods and must await confirmation. Considerable progress has been made in the development of adequate and specific methods for trace analysis of nitrosamines, and reliable information is expected in the near future.

Recent results, which have been confirmed by MS, indicate that DMN does occur in certain food products at the  $5\text{--}10\text{ }\mu\text{g kg}^{-1}$  level. Investigations undertaken on the occurrence of nitrosamines (DMNA, DENA) in meat and meat products have assessed concentration levels of  $\sim 10\text{ }\mu\text{g kg}^{-1}$ , although large amounts can be found as a result of various transformation processes (in fried bacon or smoked meat). A precursor of DMNA is the amino acid glycine. It may also originate from quaternary amino salts such as choline, acetylcholine, and betaine, which are common in meat.

Evidence of human exposure from industrial sources has been shown in air of factories that use unsymmetrical dimethylhydrazine (UDMH)-based rocket fuel. *In situ* monitoring studies have been performed in working environments. The applicability of integrated chemical/biological approaches for monitoring genotoxic hazards in different rubber factories has been proved. In particular, chemical analyses combined with a battery of genotoxicity tests, which reveal different genetic endpoints (DNA damage, point mutation, and micronuclei) have provided more information on potential health hazards in working environments in the rubber industry.

Apart from particular locations where exposure may be high, the most widespread and potent form of exposure to NOCs is via tobacco. Tobacco contains a number of alkaloids, including nicotine and in much less extent nornicotine, anatabine, and anabasine. During the curing process, the tobacco alkaloids undergo nitrosation to produce TSNAs, which are known to be amongst the most significant cancer-causing constituents of tobacco.

Recently, the presence of high levels of the potent carcinogen NDMA has been observed in drinking water supplies, especially in locations where wastewater effluents are used for indirect potable reuse. It is proved that chlorination of water and wastewater leads to the formation of relatively high concentrations of NDMA. Human exposure to *N*-nitroso compounds is not limited to their intake or exogenous exposure. Endogenous formation of nitrosamines can occur in the acidic stomach through nitrosation reactions of amines when nitrosating agents such as nitrite and nitrate are present. Nitrite is readily protonated to nitrous acid ( $\text{HNO}_2$ ) and two molecules of nitrous acid form dinitrogen trioxide ( $\text{N}_2\text{O}_3$ ), which is the actual nitrosating species that reacts with unprotonated amines to form nitrosamines. Nitrate can also contribute to nitrosation because it can be reduced to nitrite by bacteria in the mouth. Human exposure to endogenously formed NOCs has been related to an increase risk of gastric, esophageal, nasopharyngeal, and bladder cancer.

Quantitation of human exposure to endogenous NOCs can be achieved by the application of the *N*-nitrosoproline (NPRO) test. This test is based on the excretion of NPRO and other *N*-nitrosoamino acids in the urine that are measured as an index of endogenous nitrosation, following ingestion of precursors. The NPRO test has been applied to human subjects in clinical and epidemiological studies, and the kinetics and dietary modifiers of endogenous nitrosation have been investigated. Many constituents present in the human diet have been shown to inhibit endogenous formation of NOCs; for example, in studies performed with human volunteer, ascorbic acid and green tea have been shown to reduce endogenous NDMA formation. Ascorbic acid reacts faster than the amine with the nitrosating agent reducing nitrous acid to nitric oxide (NO), which is not directly a nitrosating agent. Tea polyphenols also inhibit nitrosation by competing with secondary amines for nitrosating species; the phenolic groups are then oxidized to quinone moieties.

## Sources and Occurrence

The main route for the formation of NOCs is by nitrosation reactions that take place between a nitrosating agent like nitrite ( $\text{NO}_2^-$ ) in an acidic environment, nitrous acid ( $\text{HNO}_2$ ), nitrogen oxides ( $\text{NO}_2$  or  $\text{NO}_x$ ), nitrosyl chloride (NOCl), and, on the other hand, a nitrosable agent like some amines, amides, guanidines, urea, and urethane compounds.

The nitrosation mechanism is believed to be responsible for the formation of NOCs in some foods,

such as vegetables, fish, and especially meat products cured with nitrite to prevent the growth of *Clostridium botulinum*, the bacterium that generates botulism toxin. Reactions similar to nitrosation also can occur in the atmosphere. Combustion often results in the formation of nitrogen-containing species (i.e.,  $\text{NO}_x$  or nitroso radicals) that reacts with species such as dimethylamine, released by industrial sources, to produce nitrosamines. Gas-phase nitrosation may explain the occurrence of NDMA in cigarette smoke, malt beverages, dried foods, and rubber products.

Occupational exposures to some NOCs are high in the tyre and rubber industries where nitroso radicals in engine exhaust react with amine-containing accelerators used for vulcanization. Occurrence of volatile nitrosamines, mainly NDMA and *N*-nitrosomorpholine, in work room air in the rubber and tyre industries have been detected at trace levels, in the range of  $1\text{--}10\text{ }\mu\text{g m}^{-3}$ , and sometimes higher than the maximum exposure level for some European countries ( $1\text{ }\mu\text{g m}^{-3}$ ) and over the German target value for rubber vulcanization ( $2.5\text{ }\mu\text{g m}^{-3}$ ).

NOCs are also observed in wastewater effluents in a variety of industrial plants manufacturing amines, herbicides, pesticides, pharmaceuticals, and rubber. Concentrations up to  $2\text{ mg l}^{-1}$  have been detected in wastewater effluent of a tyre factory in Ontario.

Fertilization of arable lands and grassland soils with mineral nitrogen favors the formation of nitrosamines in soil. Formation of nitro and nitroso and other compounds has been observed, which are precursors of nitrosamines. They are also products of biotransformation of some pesticides and other precursors. Dynamics of the formation and development of nitrosamine precursors in soil depend on many physicochemical factors but soil acidification processes undoubtedly favor it. Once they are formed they remain in soils for between 90 and 128 days and in aquatic environment for 80–110 days.

Of recent interest has been the detection of NDMA in groundwater in Sacramento Country, CA, at concentrations as high as  $0.4\text{ mg l}^{-1}$ , which forced the closure of drinking water wells. Initially, the presence of NDMA at so high concentrations was associated to the proximity to facilities that used UDMH-based fuels. Oxidation of UDMH by different oxidants yields NDMA as by-product. Further survey studies have demonstrated, however, that the presence of NDMA in drinking water can be associated with chlorine disinfection of water and wastewater. The formation of NDMA during chlorination can be

explained by the slow reaction of monochloramine with dimethylamine to form UDMH as intermediate, which is rapidly oxidized by monochloramine or other oxidants to form NDMA. Other nitrogen organic compounds also present in the wastewaters such as tertiary amines with dimethylamine functional groups also serve as NDMA precursors.

## Introduction

Nuclear magnetic resonance spectroscopy (NMRS) has become a useful tool for the nondestructive analysis of small samples and increasingly for non-invasive *in vivo* tissue analysis. In this article, an overview of the theory, equipment, and methodologies of NMRS are presented.

## Theory

The interaction of certain atomic nuclei with a strong magnetic field gives rise to the NMR signal and consequently NMR spectra. This section contains a brief overview of the physics of signal generation leading onto a discussion of the physics behind the specific structure of NMR spectra.

### The Physics of NMR

Atomic nuclei that have odd mass numbers and/or odd atomic numbers possess a nonzero quantum spin number,  $I$ , made up of the vector sum of the spins of its constituent protons and neutrons. The component of the vector  $I$  along an arbitrarily defined axis ( $z$  in this case) has a magnitude  $I_z$  given by

$$I_z = m_I \hbar \quad [1]$$

where  $\hbar$  is Planck's constant divided by  $2\pi$ . The quantum number  $m_I$  can take  $(2I + 1)$  values (such that  $m_I = -I, -(I - 1), \dots, [I - 1], I$ ); one can only measure a component of  $I$  in any one direction at any one time. The nuclei most commonly probed in NMR experiments ( $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^{13}\text{C}$ , and  $^{19}\text{F}$ ) have  $I = 1/2$  and so  $m = \pm 1/2$ . These two states are normally energy

degenerate. However, in the presence of a strong magnetic field,  $B_0$ , applied along the same arbitrarily defined  $z$ -axis as in eqn [1], the strong field Zeeman effect causes the states to split into two energy levels separated by energy  $\Delta E$ :

$$\Delta E = \gamma \hbar B_0 \quad [2]$$

The gyromagnetic ratio,  $\gamma$ , is defined as the ratio of magnetic moment to angular momentum of the nucleus and impacts on the sensitivity of NMRS experiments. Assuming that the coupling between the individual spins is weak, the relative populations of the two levels are given by a Boltzmann distribution:

$$\frac{n_{\uparrow}}{n_{\downarrow}} = \exp \left[ \frac{\Delta E}{kT} \right] \quad [3]$$

where  $k$  is the Boltzmann constant and  $T$  is the temperature of the spin system. A collection of spins will distribute themselves between the energy levels resulting in a small excess of spins in the lower ( $n_{\uparrow}$  – spin up) state at thermal equilibrium. This leads to a sample obtaining a net magnetization,  $M_0$ , lying parallel to the main field. This is the property that is detectable using NMR and its amplitude is dependent on  $\gamma^2$ ,  $B_0$ , and the number of equivalent nuclei per unit volume,  $n$ :

$$M_0 = \frac{n \gamma^2 \hbar^2 B_0}{4kT} \quad [4]$$

As  $M_0$  is a property of the bulk system, one can define all three components simultaneously and use classical mechanics to describe its evolution.  $M_0$  will precess around  $B_0$  at the Larmor frequency,  $\omega_0$  (see Figure 1). The Larmor frequency is equivalent to the frequency of photons required to induce transitions between the energy levels and is defined as:

$$\omega_0 = \gamma B_0 \quad [5]$$

Manipulation of the orientation of  $M_0$  relative to  $B_0$  using circularly polarized radio frequency (RF) at this resonant frequency leads to the generation of the NMR signal. To illustrate this it is commonplace to

**Figure 1** The net magnetization of the sample  $M_0$  will precess around the applied magnetic field vector with an angular frequency  $\omega_0$ . This is equivalent to the frequency of RF required to stimulate a transition between the spin-up and spin-down energy states.

define a set of axes rotating about  $B_0$  at the Larmor frequency. With the introduction of RF at this frequency, right-hand circularly polarized along the  $z$ -axis, the equivalent magnetic field in this frame,  $B_1$ , becomes oriented in the  $x'$ - $y'$  plane and has an amplitude equal to the amplitude of the B-field component of the RF.  $M_0$  will precess around  $B_1$  with a frequency  $\omega_1$  equivalently to eqn [5] (see **Figure 2**). By adjusting the length and power of the RF pulse it is possible to flip  $M_0$  vector into the  $x'$ - $y'$  plane; this is equivalent to equalizing the populations of the quantum mechanical energy levels and is known as a  $90^\circ$  pulse. The amplitude of the NMR signal is proportional to the component of  $M_0$  in the  $x$ - $y$  plane and its precession about  $B_0$  causes an oscillating current to be induced in a suitably arranged RF coil (described below). This signal decays exponentially with a time constant  $T2^*$  due to field inhomogeneities causing spins to precess at different rates and dephase. The result is a free induction decay (FID) (see **Figure 3**).

### Chemical Shift

NMR spectra consist of a series of peaks identifiable to specific chemical structures on particular molecules rather than just a single peak resonating at  $\omega_0$ ; the position of a peak in the spectrum is termed its chemical shift. Peaks occur at different chemical shifts because the magnetic field at an atomic nucleus is not

**Figure 2** The tilting of  $M_0$  into the  $x'$ - $y'$  frame due to the application of RF at the Larmor frequency  $\omega_0$ . This is represented in a frame of reference rotating about  $B_0$  at  $\omega_0$ . The equivalent field in the rotating frame is  $B_1$ , which appears stationary along  $y'$ .  $M_0$  precesses  $B_1$  with an angular frequency  $\omega_1$ .

**Figure 3** An example of FID consisting of a single frequency decaying exponentially.

equal to the applied magnetic field. The electrons in electronic orbitals shield the nucleus from the applied field, thus altering the resonant frequency. Electrons in atoms and molecules are described by a series of quantum numbers. Technically, the shape of an atomic orbital occupied by an electron with a given set of quantum numbers is best described by the square of its quantum mechanical wavefunction.

**Figure 4** Shielding of the nucleus from the applied magnetic field due to an orbital  $s$ -electron. The current due to the electron induces a magnetic field at the nucleus that acts to oppose the applied field.

The principal quantum number,  $N$ , is dominant in determining the shape of an orbital; for a rigorous treatment of quantum mechanics and the physics of electronic orbitals, the reader can refer to the Further Reading. For the purpose of this discussion it is sufficient to recognize that  $s$ -orbitals ( $N=1$ ) have a spherical symmetry and higher orbitals ( $p$ ,  $N=2$ ;  $d$ ,  $N=3$ ; etc) have more complex shapes. Thus the simplest example of nuclear shielding is that arising from electrons in  $s$ -orbitals. A schematic of how an  $s$ -electron shields the nucleus is shown in **Figure 4**. In the presence of an applied field, the electron's orbital forms an effective current loop resulting in a magnetic field that opposes the applied field. Thus the nucleus experiences a reduced magnetic field and resonates at a lower frequency. The magnitude in hertz of the chemical shift is proportional to the size of the applied field, as this determines the magnitude of the effective currents produced by the electrons. In order to eliminate the dependence on  $B_0$ , chemical shifts are generally quoted in units of parts per million (ppm) of the static magnetic field strength.

### Proton Chemical Shifts

Only  $s$ -electrons have orbitals around hydrogen nuclei. However, the degree of shielding that they provide is further influenced by their chemical environment. Electronegative elements near to the proton withdraw electron density and reduce the extent of the shielding. An example of oxygen bonded to carbon influencing the chemical shifts of the protons also bonded to the carbon is shown in **Figure 5**. The larger the electronegativity of the directly bonded atom, the larger its influence on the chemical shift of its NMR visible neighbors. Double bonds ( $\pi$ -bonds) between carbon atoms in organic molecules also have a significant effect on proton chemical shift.

**Figure 5** Electronegative elements such as oxygen draw electron density toward them reducing the shielding of the proton.

**Figure 6** (A)  $\pi$ -Bonds between carbon atoms can lead to the magnetic field at a proton being enhanced when oriented in the plane perpendicular to the main field. (B) An exception is the terminal alkyne. In this example the shielding is increased.

For a portion of their time, these molecules will be oriented with their  $\pi$ -bonds perpendicular to applied field, as illustrated in **Figure 6**. The current distribution of the  $\pi$ -electrons is such that a magnetic field is produced that opposes the applied field above and below the bond, but reinforces the applied field at the attached proton. An exception to this is the terminal alkyne group (**Figure 6**), where the proton is oriented in the same plane as the  $\pi$ -bond. The major contribution comes when the  $\pi$ -bond is oriented parallel to the applied field. The current distribution from the  $\pi$ -electrons leads to an induced field that opposes the applied field at the proton. All of the above effects are additive in determining the final chemical shift of a proton and the position of resonances can be suggestive of specific function groups (see **Table 1**).

### Other Nuclei and Chemical Shift Mechanisms

Nuclei other than  $^1\text{H}$  that are typically used for NMRS, such as  $^{31}\text{P}$  and  $^{13}\text{C}$ , have electrons in higher orbitals that do not have spherical symmetry. These can produce comparatively large magnetic fields at the nucleus. Thus the range of chemical shifts is larger; typically, the range of chemical shifts for  $^{13}\text{C}$  (0–200 ppm) is 10–20 times the range of proton chemical shifts. The chemical shifts of some resonances are variable depending on the environment of

**Table 1** The chemical shift of a peak can indicate the type functional group producing the peak.

Chemical name	Functional group	Approximate chemical shifts relative to TMS (ppm)
Alkanes	$\text{R}-\text{CH}_3$	0.5–2
Alkenes	$\begin{array}{c} \diagup \\ -\text{C}=\text{C} \\ \diagdown \quad \diagup \\ \quad \quad \text{CH} \\ \quad \quad   \end{array}$	2–4
Alkynes	$-\text{C}\equiv\text{C}-\text{H}$	1.5–3
Alcohols	$\text{ROH}$	3–5
Aldehydes	$\begin{array}{c} \text{H} \\   \\ -\text{C} \\    \\ \text{O} \end{array}$	9.5–10
Carboxylic acids	$\begin{array}{c} \text{OH} \\   \\ -\text{C} \\    \\ \text{O} \end{array}$	10–12

Chemical shifts are expressed relative to that of tetramethylsilane (TMS) at 0 ppm

the sample. Hydrogen bound (acid) and unprotonated (base) chemicals have different chemical shifts. As the acid and base states are in rapid chemical exchange, a single resonance with the average chemical shift of the relative equilibrium populations is observed. The local concentration of hydrogen ions (and hence pH) determines the acid–base populations and so alters the chemical shift. Similarly, metal-ion concentration can influence chemical shift. Uncomplexed adenosine triphosphate (ATP) is observable using  $^{31}\text{P}$  spectroscopy. Free intracellular magnesium exists in equilibrium with complexed MgATP and so the observable ATP chemical shifts are sensitive to changes in free intracellular magnesium levels. Temperature is also important as increases in temperature lead to intensification of molecular motion. The chemical bonds weaken altering the degree of nuclear shielding. Thus the resonant frequency decreases. The  $^1\text{H}$  chemical shift of water has an almost linear dependence on temperature between  $0^\circ$  and  $40^\circ$  changing by approximately  $-0.01 \text{ ppm}^\circ\text{C}^{-1}$ .

### Spin–Spin Coupling

Spins of adjacent nuclei affect resonance energy levels, splitting the observed peaks into various multiplet structures. The coupling is not direct but is mediated by electrons in the chemical bonds between nuclei and allows a given nucleus to ‘sense’ the spin states of its neighbors. The coupling can be between

**Figure 7** The chemical structure and multiplets of lactate. The  $\text{CH}_3$  group produces the doublet at 1.31 ppm. The  $\text{CH}$  group produces the quartet at 4.1 ppm. Spectra were acquired on a 7 T Bruker Biospec spectrometer.

similar (homonuclear) or different nuclei (heteronuclear). However, chemically equivalent protons do not couple to each other. The chemical structure of lactate is shown in **Figure 7** with its corresponding  $^1\text{H}$  spectrum consisting of two resonances, a doublet and a quartet due to the  $-\text{CH}_3$  and  $-\text{CH}$  protons, respectively. The  $-\text{CH}$  proton has two possible spin orientations, parallel or antiparallel to  $\mathbf{B}_0$ , and is constantly changing between the spin states. Half of the time the  $-\text{CH}_3$  protons will sense the  $-\text{CH}$  proton parallel state and the remaining time the antiparallel state. The spin states of the  $-\text{CH}$  proton are at slightly different energy levels and due to electron mediation a slight change in the local magnetic field is experienced by the three equivalent  $-\text{CH}_3$  protons. Across the whole sample this results in a doublet with components of approximately equal amplitude. The  $-\text{CH}$  proton experiences eight possible combinations for the  $-\text{CH}_3$  protons, these are illustrated in **Figure 8**. However, some of these combinations are indistinguishable resulting in four effective combinations of spin states. The result is the quartet with the relative amplitudes of the components depending on the relative probabilities of the possible states,  $\sim 1:3:3:1$ . The total intensity of the doublet is three times that of the quartet as there are three times as many equivalent protons contributing to the resonance. The separation of multiplet components is known as the coupling constant  $J$ . This is measured in hertz and is independent of the applied field strength.

### Phase Modulation

Where a spectrum is obtained using a sequence that involves acquiring an echo rather than direct

observation of the signal following excitation, spin-spin coupling affects the amplitudes and phases of spectral peaks. Consider the case of the lactate doublet observed using a spin-echo experiment with the resonant frequency,  $\omega_0$ , set half way between the two peaks for convenience (see Figure 9). In a frame of reference rotating at  $\omega_0$ , the spins in each peak of the doublet will disperse away from each other. Spins also dephase because of inhomogeneity in the main field. A  $180^\circ$  pulse applied along the  $y$ -axis has the

effect of flipping the spins about this axis. Subsequently, the dephasing due to applied field inhomogeneity is refocused. However, the dephasing due to spin coupling is not refocused and the components of the lactate doublet will fall out of phase with other uncoupled signals in the spectrum. The echo time, TE, of a sequence is the time between excitation of the spin system and formation of the echo. At TE the components of the doublet are separated in phase,  $\phi$ , by:

$$\phi = 2\pi/TE \quad [6]$$

In the case of the lactate doublet,  $J = 7$  Hz. If a spin echo is acquired at TE = 135 ms, the doublet will appear inverted relative to the prominently visible singlets (see Figure 10).

**Figure 8** The spin-spin coupling of lactate. The three protons in the  $CH_3$  group can arrange themselves in eight different combinations of orientations. Arrangements with two spins 'up' are all equivalent with respect to their effect on the CH proton. The result of spin coupling is that the peak from the CH group splits into a quartet with the middle two components being three times the amplitude of the outer two components. The  $CH_3$  peak splits into a doublet.

## Equipment

The specific hardware used for NMRS studies is dependent on the application but is generally very similar to that used for medical magnetic resonance imaging studies.

### Magnet and Shim Coils

The central piece of equipment is the magnet that generates the static magnetic field. The strength of the applied magnetic field is the main variable that can be exploited to improve the sensitivity of NMRS experiments. Persistent superconducting magnets are the most common type used. These have coil windings made of superconducting material through

**Figure 9** The phase modulation of the lactate doublet due to spin coupling. The view is of the  $x'$ - $y'$  rotating frame with the rotation frequency set halfway between the two spectral components. (A) The two components phase modulate away from each other and spins in each component de-phase because of field inhomogeneities. (B) Following a  $180^\circ$  pulse, which flips the spins about the  $x'$ -axis, the dephasing of the spins due to field inhomogeneities is refocused. However, the phase modulation due to spin coupling is not refocused. Eventually the doublet will become  $180^\circ$  out of phase with its original orientation.

**Figure 10** A  $^1\text{H}$  spectrum from a chick brain *in vivo* at 135 ms echo time. The major peaks are labeled and lactate is inverted relative to the uncoupled peaks in the spectrum. Spectrum taken using a 7 T Bruker Biospec spectrometer.

which the energizing current flows continuously. The materials that are used for these windings must be kept below their critical temperature for superconductivity and are immersed in liquid helium for this purpose. The presence of a magnetic field lowers the critical temperature placing a limit on the field achievable using a particular material. Niobium–titanium alloy is commonly used and can support a field up to 10 T in liquid helium; newer materials offer even better performance. Horizontal bore systems, suitable for *in vivo* use, are currently available up to  $\sim 11$  T. Vertical bore systems, suitable for high-resolution NMRS of samples, are currently available up to 21 T. The stability of superconducting magnets is very good with field drift typically less than  $0.05 \text{ ppm h}^{-1}$ . Equally as important as stability is the uniformity of the magnetic field. Spatial inhomogeneities in the magnetic field mean that a resonance at a specific ppm will have a different actual resonance (in hertz) depending on its location within the field. The result is that spectral lines are broadened and resolution between lines is lessened. Typically the nonuniformity over the region of interest must be less than the minimum chemical shift it is desired to resolve. A magnet may have a set of superconducting coils to shim (remove inhomogeneities from) the main field; currents in these coils are established that produce magnetic fields that oppose the inhomogeneities in field produced by the main coil. Introducing a sample into the magnet poses an additional problem, especially for *in vivo* samples. Boundaries between materials of different magnetic susceptibility generate field gradients that lead to broadening of spectral lines. These are corrected for by adjusting the currents in a set of

room temperature resistive shim coils. Typically the observation of the linewidth of a prominent spectral line is used as feedback for the iterative adjustment of these shim currents.

### Gradient Coils

In the case of a narrow bore vertical spectrometer designed for studying homogeneous samples, signals are typically collected from the whole of the sample. However, when studying heterogeneous samples, typically *in vivo* samples in a wide bore horizontal spectrometer, it is often necessary to localize the acquisition of signal to specific structures within the sample. The methods for localization are similar to those used in magnetic resonance imaging and involve the use of sequences of temporally applied field gradients along with RF. Spectrometers for medical applications include gradient coils that are designed to produce field gradients in three orthogonal directions. Gradient coils also allow for an imaging as well as a spectroscopy capability.

### RF Coil

RF coils are resonant circuits that are designed to produce oscillating magnetic fields with a suitable geometry to excite a sample and reciprocally to detect the subsequent NMR signal. The choice of coil is strongly influenced by the application for which it is to be used. In the simplest arrangement, a single coil is used to both transmit RF and to detect the signal. Alternatively, it may be advantageous to use one coil for excitation, typically a volume coil generating a uniform oscillating field, and one for signal detection whose geometry is matched to a region of interest in the sample, particularly *in vivo*. For a coil to work efficiently it must be tuned to the resonant frequency of the nuclei under investigation and impedance matched to the transmitter, receiver, or both depending on the mode of operation. Often a coil will be designed to tune to both the proton resonant frequency and that of the nuclei under investigation or be used in conjunction with a second coil tuned to protons. The larger NMR signal from protons is typically used to provide interactive feedback whilst shimming.

## Signal Acquisition and Processing

When the FID is acquired, it is mixed with an artificially generated reference signal so as to convert the RFs to the audio frequency range. The frequencies contained in the converted signal are now equivalent to the difference between the original signal and the reference. Thus if the original signal contains simply

a frequency  $\nu_1$  and was mixed with a reference  $\nu_r$ , the resulting signal would be  $(\nu_1 - \nu_r)$ . It is this converted signal that is then sampled and processed to produce the final spectrum. The signal is sampled into two channels that correspond to the projection of  $\mathbf{M}_0$  along orthogonal directions in the  $x$ - $y$  plane. If a quadrature coil is used the data in these channels are measured independently. If a single channel coil-receiver arrangement is used then the second channel is simulated. These two channels, termed real and imaginary, have a  $90^\circ$  phase difference and are combined to form a complex dataset. This is then Fourier transformed and, following a suitable phase adjustment, the real component is displayed as the final spectrum.

### Dwell Time and Sampling Time

The NMR signal is sampled continuously over the acquisition time,  $T$ , with a dwell time between samples  $\Delta t$ . For a given dwell time a signal can only be unambiguously identified if its frequency  $\nu$  is below a critical threshold termed the Nyquist frequency. Above the Nyquist frequency, signals will be aliased (see Figure 11). Aliasing occurs when a high frequency appears to look like a low frequency because the sampling rate is too low, thus the signal is misrepresented or aliased as the lower signal. If quadrature detection is used, then negative frequencies

can be distinguished from positive frequencies and the spectral width, SW - the range of frequencies that can be unambiguously detected, is centered round the reference frequency and covers the interval:

$$-\frac{1}{2\Delta t} < \nu_r < \frac{1}{2\Delta t} \quad [7]$$

For one-channel detection it is impossible to distinguish between positive and negative frequencies and so SW covers the interval  $0 < \nu_r < 1/2\Delta t$ . The acquisition time determines the spectral resolution of the final spectrum,  $\Delta\nu$ :

$$\Delta\nu = \frac{1}{T} \quad [8]$$

The acquisition parameters  $T$ ,  $\Delta t$ , and  $\nu_r$  are chosen so as to have an SW sufficiently large and properly centered to cover the chemical shift range of the spectrum with an appropriate spectral resolution.

### Filtering the FID

Often it is desirable to apply a filter to the digitized FID. Sometimes the sampling of the FID is completed before reaching the noise level and can be thought of as multiplying a complete FID by a step function. Fourier transforming these two functions would give a convolution of the spectrum with a sinc function producing lineshape distortions. A function can be applied to smooth the FID to zero within the acquisition period. Typically the FID is multiplied by a decaying exponential function. The resulting spectrum will be convoluted with Lorentzian function, the Fourier transform of the decaying exponential, resulting in the removal of the artifact but at the cost of broadening the spectral components. This technique is also used to improve the signal-to-noise ratio (SNR) of a spectrum but with the same costs.

Broad spectral components have large amplitudes in the first few digitized points of the FID, whereas narrow spectral components have longer signals. It is often advantageous to suppress these broad components. If the signal at the start of FID is reduced then the broad components are reduced relative to the narrow components. A suitable function to use is the linear ramp. The function increases from zero to one over the first few points and is used to multiply the FID. A further consequence is to apparently increase the decay constant  $T_2^*$ , resulting in narrower spectral lines. The cost is to increase the level of the noise relative to the signal in the FID resulting in a noisier spectrum. When filtering, there are always trade offs between spectral resolution and SNR; resolution enhancement leads to SNR degradation and vice versa.

**Figure 11** Data sampling. The solid line represents a wave that is sampled at a rate sufficient to identify its frequency. The dashed line represents a wave with a frequency that is above the Nyquist limit. The frequency of this wave cannot be properly identified and will be aliased as having a frequency equal to that of the solid line.

## Zero Filling

Once the FID has decayed below the noise level there is little more useful information that can be gained. However, increasing the number of data points at the end by filling with zeros can improve spectral resolution. The apparent increased sampling results, after Fourier transform, in a spectrum with more data points consequently improves the visibility of otherwise unresolved peaks. Filtering of the FID is usually applied before zero filling to avoid truncation artifacts.

## Analysis Methods

Analysis of NMR spectra may be performed on either the FID (in the time domain) or on the Fourier transformed spectrum (in the frequency domain). Determining the chemical shift and  $J$ -coupling of spectral peaks aids the identification of constituent molecules present in a sample, the measurement of physiological parameters such as pH, and also the determination of chemical structure of specific molecules. An analysis technique must be reliable, objective, and ideally fully automatic. It must also be able to cope with spectral imperfections and be accurate in accounting for lineshape distortions, phase modulation effects, and determining the baseline upon which the peaks sit. Spectra obtained *in vivo* typically do not have the resolution of *in vitro* biological or inorganic samples studied at high field and, for  $^1\text{H}$  NMRS in particular, peaks will overlap to a greater degree. The method of analysis chosen reflects both the application and the inherent limitations of the experiment. Below are brief descriptions of two commonly used analysis methods.

### Analysis in the Time Domain (Linear Combination of Decaying Exponentials)

Time domain analysis avoids the need for a Fourier transform prior to processing. The first few data points, in which signals from rapidly decaying immobile nuclei are mostly contained, and the last few that are at the noise level can be ignored in the analysis, leaving a section of FID that has good SNR and has a simplified baseline. Algorithms such as time domain analysis algorithm (VARPRO) and time domain analysis method (AMARES) are usually used to fit a sum of exponentially decaying sinusoids to the FID using nonlinear least squares. Prior knowledge is used to aid the fitting procedure. The precision of the fit may be significantly improved by fixing parameters whose values are known *a priori* such as the multiplicity,  $J$ -coupling, and relative intensities of a multiplet.

### Analysis in the Frequency Domain (LCModel)

LCModel is a widely used method of analysis, especially for *in vivo*  $^1\text{H}$  spectra. Spectra are analyzed as a linear combination of model spectra of metabolite solutions *in vitro*. The model spectra provide *a priori* information about chemical shifts, relative areas, number of equivalent protons, and phase modulation effects. However, these spectra must be obtained for each echo time at which *in vivo* spectra are to be obtained. A full basis set is required for the analysis at each specific echo time and consists of model spectra for all the metabolites that are likely to be observed *in vivo*. The method is model-free such that smooth lineshapes and baselines consistent with the data are determined rather than assumed.

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy is a rich source of molecular information. It is widely used for molecular structure analysis and for medical imaging under the name MRI (magnetic resonance imaging). NMR is a nondestructive quantitative method for the analysis of complex mixtures such as reactions, petroleum, materials, and foods. It finds major application in the determination of molecular structure and dynamics, especially of pharmaceuticals, polymers, and proteins. Diverse applications include measurement of internuclear distances, water content of food, characterization of oil deposits using the earth's magnetic field, *in vivo* studies of metabolic pathways in cells and humans, diffusion of adsorbates into porous materials, reaction dynamics, fluid flow, generation and measurement of temperatures in the millikelvin range, and online monitoring of manufacturing processes. Samples may be gases, liquids, or solids.

This article provides a description of the basic principles of NMR spectroscopy. The many applications of this technique, which make it indispensable as a tool for the analytical chemist, are described in subsequent articles, which also include discussion of advanced techniques such as the NMR of solids, multidimensional NMR, and MRI.

### Principles of NMR

NMR detects signals from nuclei in atoms and molecules when they are excited in a strong homogeneous magnetic field ( $B_0$  in tesla). NMR was invented independently by Bloch and Purcell to accurately measure nuclear magnetic moments ( $\mu$ ). It is now used to measure magnetic field strength with high precision based on known  $\mu$  values.

The nuclear magnets are ordered into  $2I + 1$  states determined by the nuclear spin quantum number  $I$ . The spin angular momentum is quantized in units of  $\hbar$  and the change in the  $z$  component is detected in the NMR experiment. For many common NMR nuclei  $I = 1/2$  ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{19}\text{F}$ ,  $^{29}\text{Si}$ ,  $^{31}\text{P}$ ) and there are two allowed states labeled spin up and spin down. Irradiation with radiofrequency (RF) electromagnetic radiation ( $\nu$  in Hz) causes spin flip transitions provided the resonance condition is satisfied:

$$h\nu = \hbar\gamma B_0 = \mu_z \beta B_0 \quad [1]$$

where  $h$  is Planck's constant ( $6.62608 \times 10^{-34}$  Js),  $\hbar = h/(2\pi)$ ,  $\beta$  is the nuclear Bohr magneton ( $eh/4\pi m_p = 5.0508 \times 10^{-27}$  J T $^{-1}$ ) and  $\mu_z$  is the  $z$ -component of the total moment  $= \sqrt{I(I+1)}\mu_z$ . The nuclear magnetogyric ratio ( $\gamma$  in rad s $^{-1}$  T $^{-1}$ ) is an exquisitely sensitive discriminator between elements and also of the immediate electronic environment of each nucleus. Tables list values of  $\mu$  in units of  $\beta$  according to different conventions. For protons, the values are 5.5854 with  $\mu = \gamma\hbar$ ; 2.7927 with  $\mu_z = \gamma\hbar I$  for the  $z$ -component of spin  $I$ ; or 4.8372 with  $\mu = \gamma\hbar\sqrt{I(I+1)}$  for the total magnetic moment.

The common information obtainable from an NMR spectrum is summarized in Table 1 and illustrated with the proton NMR spectrum of ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) (Figure 1). The horizontal axis, which gives the 'chemical shift' of the signal, is a linear frequency scale in hertz, which is almost always converted to the dimensionless  $\delta$  scale (ppm) with tetramethylsilane (TMS) as reference at  $\delta = 0.000$ . The  $\delta$  scale is independent of magnetic field strength and so is transferable from spectrometer to spectrometer. It is defined as

$$\delta_i = \Delta\nu_i/\nu_{\text{ref}} \quad [2]$$

where  $\nu_{\text{ref}}$  is the absolute resonance frequency of TMS (e.g., 200.010078 MHz in a field of 4.70 T) and  $\Delta\nu_i = \nu_i - \nu_{\text{ref}}$  is the difference between the frequency of the nucleus of interest ( $\nu_i$ ) and  $\nu_{\text{ref}}$ . The vertical axis is a linear relative intensity scale that is generally proportional to the number of nuclei in the resonant

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy is a rich source of molecular information. It is widely used for molecular structure analysis and for medical imaging under the name MRI (magnetic resonance imaging). NMR is a nondestructive quantitative method for the analysis of complex mixtures such as reactions, petroleum, materials, and foods. It finds major application in the determination of molecular structure and dynamics, especially of pharmaceuticals, polymers, and proteins. Diverse applications include measurement of internuclear distances, water content of food, characterization of oil deposits using the earth's magnetic field, *in vivo* studies of metabolic pathways in cells and humans, diffusion of adsorbates into porous materials, reaction dynamics, fluid flow, generation and measurement of temperatures in the millikelvin range, and online monitoring of manufacturing processes. Samples may be gases, liquids, or solids.

This article provides a description of the basic principles of NMR spectroscopy. The many applications of this technique, which make it indispensable as a tool for the analytical chemist, are described in subsequent articles, which also include discussion of advanced techniques such as the NMR of solids, multidimensional NMR, and MRI.

### Principles of NMR

NMR detects signals from nuclei in atoms and molecules when they are excited in a strong homogeneous magnetic field ( $B_0$  in tesla). NMR was invented independently by Bloch and Purcell to accurately measure nuclear magnetic moments ( $\mu$ ). It is now used to measure magnetic field strength with high precision based on known  $\mu$  values.

The nuclear magnets are ordered into  $2I + 1$  states determined by the nuclear spin quantum number  $I$ . The spin angular momentum is quantized in units of  $\hbar$  and the change in the  $z$  component is detected in the NMR experiment. For many common NMR nuclei  $I = 1/2$  ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{19}\text{F}$ ,  $^{29}\text{Si}$ ,  $^{31}\text{P}$ ) and there are two allowed states labeled spin up and spin down. Irradiation with radiofrequency (RF) electromagnetic radiation ( $\nu$  in Hz) causes spin flip transitions provided the resonance condition is satisfied:

$$h\nu = \hbar\gamma B_0 = \mu_z \beta B_0 \quad [1]$$

where  $h$  is Planck's constant ( $6.62608 \times 10^{-34}$  Js),  $\hbar = h/(2\pi)$ ,  $\beta$  is the nuclear Bohr magneton ( $eh/4\pi m_p = 5.0508 \times 10^{-27}$  J T $^{-1}$ ) and  $\mu_z$  is the  $z$ -component of the total moment  $= \sqrt{I(I+1)}\mu_z$ . The nuclear magnetogyric ratio ( $\gamma$  in rad s $^{-1}$  T $^{-1}$ ) is an exquisitely sensitive discriminator between elements and also of the immediate electronic environment of each nucleus. Tables list values of  $\mu$  in units of  $\beta$  according to different conventions. For protons, the values are 5.5854 with  $\mu = \gamma\hbar$ ; 2.7927 with  $\mu_z = \gamma\hbar I$  for the  $z$ -component of spin  $I$ ; or 4.8372 with  $\mu = \gamma\hbar\sqrt{I(I+1)}$  for the total magnetic moment.

The common information obtainable from an NMR spectrum is summarized in Table 1 and illustrated with the proton NMR spectrum of ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) (Figure 1). The horizontal axis, which gives the 'chemical shift' of the signal, is a linear frequency scale in hertz, which is almost always converted to the dimensionless  $\delta$  scale (ppm) with tetramethylsilane (TMS) as reference at  $\delta = 0.000$ . The  $\delta$  scale is independent of magnetic field strength and so is transferable from spectrometer to spectrometer. It is defined as

$$\delta_i = \Delta\nu_i/\nu_{\text{ref}} \quad [2]$$

where  $\nu_{\text{ref}}$  is the absolute resonance frequency of TMS (e.g., 200.010078 MHz in a field of 4.70 T) and  $\Delta\nu_i = \nu_i - \nu_{\text{ref}}$  is the difference between the frequency of the nucleus of interest ( $\nu_i$ ) and  $\nu_{\text{ref}}$ . The vertical axis is a linear relative intensity scale that is generally proportional to the number of nuclei in the resonant

**Table 1** Basic information in an NMR spectrum

Observable	NMR parameter	Symbol (units)	Chemical information
Peak position	Chemical shift	$\delta$ (ppm) (absolute Hz)	Functional group identification
Peak multiplicity	Coupling constant	$J$ (Hz)	Number and type of nuclei within three bonds of the nucleus being detected
Peak intensity	Integrated area		Count of nuclei of given type
Lineshape and linewidth	Spin–spin relaxation time	$T_2 = (1/\pi\Delta\nu)$ (s) Peak width at half-maximum intensity ( $\Delta\nu$ , Hz)	Lifetime of spin state determined by dynamic processes and local magnetic environment
Time dependence of intensity <sup>a</sup>	Spin–lattice relaxation time and nuclear Overhauser effect (nOe)	$T_1$ (s), nOe	Molecular dynamics and magnetic interactions

<sup>a</sup>Not shown in **Figure 1**. Requires repetitive experiments.

**Figure 1** 200 MHz proton NMR spectrum of ethanol containing water (13 mol.%) and tetramethylsilane (TMS) as reference. The inset shows dry ethanol with OH coupling. Splitting diagrams are shown over each multiplet. The upper scale is in Hz and lower scale in  $\delta$ /ppm. SSB indicates spinning side-bands, which are separated from the main peaks by the spinner frequency. The  $^{29}\text{Si}$  satellites on the TMS resonance arise from  $^1\text{H}$ – $^{29}\text{Si}$  coupling.  $^{29}\text{Si}$  ( $I = 1/2$ ) is present at 4% natural abundance. (Spectrum courtesy of Dr J. Hopkins.)

chemical group. More precisely, it is the relative magnitude of the magnetization precessing at the frequency of interest.

The spectrum of ethanol shown in **Figure 1** consists of five signals – a single sharp peak at  $\delta = 0.0$  from the TMS added as reference, a triplet at  $\delta = 1.16$  for the methyl group, a quartet at  $\delta = 3.61$  for the methylene group, and broad singlets at  $\delta = 5.41$  and  $4.62$ , which are the signals from the alcohol OH and the water present as a ‘contaminant’. An integral curve is shown above the spectrum giving the integrated area under each peak. Each

integral is normalized to the methyl peak intensity of 3.0 and gives the proton count in each group. The fine structure within each multiplet is generated by the  $n$  protons within three bonds of the observed proton. The multiplet intensity pattern is governed by the statistical probability of the  $2nI + 1$  possible spin arrangements of the neighboring nuclei. As  $I = 1/2$  for protons,  $n$  neighboring protons cause splitting into  $n + 1$  peaks with binomial intensity. The spacing within each multiplet is called the coupling constant,  $J$  (Hz), and the same spacing occurs in each multiplet for the pair of coupled

**Figure 2** 500 MHz  $^1\text{H}$  NMR spectrum of menthol (OD) in  $\text{CD}_2\text{Cl}_2$ . The spectra show the effects of sample size and signal averaging. Note the growing importance of solvent impurities as the sample size decreases. (Spectrum courtesy of Varian Associates.)

groups. For ethanol, the methyl group is split into a 1:2:1 triplet with  $J = 7\text{ Hz}$  by the neighboring  $\text{CH}_3$  group. Similarly, the methylene peak is split with the same spacing into a 1:3:3:1 quartet by the adjacent  $\text{CH}_3$  group. In the normal spectrum there is no coupling observed between the  $\text{CH}_2$  and OH groups because the OH bond is being broken several times per second by exchange with the water. In ultrapure ethanol (inset in **Figure 1**) when the OH exchange is slow, the  $\text{CH}_2$  group appears as a doublet (5 Hz) of quartets (7 Hz) and the OH signal is a 1:2:1 triplet with  $J = 5\text{ Hz}$ . The methyl triplet is unchanged as it is separated by four bonds from the OH.

Peak linewidths may be used to measure the spin life time. In **Figure 1**, the linewidths of the water and alcohol OH peaks are substantially broader than those from protons bound to carbon. The broadness shows that the water protons and alcohol OH are exchanging on the order of 10 times per second.

This example illustrates the power of NMR. About 0.5 ml of colorless liquid, contained in a glass tube, has been identified as ethanol containing  $\sim 15\%$  water. Less than 0.2% of other protonated impurities are present and the kinetics of proton

exchange was estimated. The whole experiment took a few seconds. Sensitivity is always an issue for NMR analysis. Millimolar solutions and milligram quantities are required for most applications. The effect of sample size on spectral quality is shown in **Figure 2**. Spectral analysis has been achieved on  $10\text{ }\mu\text{g}$  of a compound in  $0.3\text{ }\mu\text{l}$  of solution and spectra of 100 ng samples have been recorded and interpreted.

## NMR and the Periodic Table

The NMR periodic table (**Table 2**, *Bruker Almanac* (2003) Karlsruhe: Bruker Biospin) provides the nuclear properties for the main NMR active isotopes.

### Nuclear Spin Quantum Number ( $I$ )

In a magnetic field, a nucleus exists in  $2I + 1$  possible spin states. Protons and neutrons have  $I = 1/2$ . The vector sum of coupled proton and neutron spins gives the nuclear spin quantum number for each nucleus. Isotopes with an even number of both protons and neutrons may have zero spin and are NMR inactive (e.g.,  $^{12}\text{C}$ ,  $^{16}\text{O}$ ).

**Table 2** List of elements showing the nuclear properties of the main NMR-active isotopes

### Quadrupole Moment ( $Q$ , $10^{-24} \text{ cm}^2$ )

Isotopes with  $I > 1/2$  are called quadrupolar nuclei. The nucleus responds to both magnetic and electric fields. Quadrupolar nuclei respond to the electric field gradient at the nucleus through the quadrupole coupling,  $\chi$ :

$$\chi = e^2 Q q_{zz} / h \text{ (Hz)} \quad [3]$$

where  $Q$  is the intrinsic electric quadrupole moment and  $eq_{zz}$  measures the effective electric field gradient at the nucleus induced by local bonding. In a symmetrical environment, e.g.,  $^{14}\text{N}$  in the  $\text{NH}_4$  cation,  $q$  and hence  $\chi$  may be zero. For monovalent elements, e.g.,  $^2\text{H}$  and  $^{79}\text{Br}$ , the electric field gradient is directed along the bond axis and is nonzero. The spectra of quadrupolar nuclei with large  $Q$  values are usually very broad since the electric field gradient is modulated by molecular motion and the nuclear relaxation time becomes very short. The linewidth is inversely proportional to the spin lifetime, and linewidths of the order of kilohertz to megahertz are common. The spectra of spin  $1/2$  nuclei are influenced by coupling to quadrupolar nuclei. The spectra of  $^{14}\text{N}$ -H protons are often broad because the rate of interchange of the  $^{14}\text{N}$  spin states is of the same order of magnitude as the  $^{14}\text{N}$ -H spin-spin coupling. This contrasts with O-H protons, where chemical bond breaking is responsible for line broadening. For  $\text{CDCl}_3$ , D has a small  $Q$  and the carbon is split into a 1:1:1 triplet, but  $^{35}\text{Cl}$  has a large  $Q$  and relaxes very rapidly, and so no coupling between  $^{13}\text{C}$  and  $^{35}\text{Cl}$  is observed.

In solid samples, the magnitude of  $\chi$  depends on the orientation of the electric field gradient with respect to  $B_0$ . As a consequence, deuterium NMR has been developed as a sensitive probe of molecular motion in materials over the 0–125 kHz range. A novel probe capable of rotating a sample about two different axes simultaneously has been developed to obtain narrow peaks for quadrupolar nuclei in solids. Quadrupolar nuclei give narrower signals at higher fields, and pulse sequences have been developed to further narrow lines.

### Nuclear Resonance Frequency ( $\nu$ , MHz)

Table 2 lists the resonance frequencies of each nucleus in a magnetic field of 4.698 T. Protons resonate at 200.0 MHz at this field. The frequency values are equivalent to  $\gamma$  as  $\gamma = 2\pi\nu/B_0$ . For protons  $\gamma = 26.7519 \times 10^7 \text{ rad T}^{-1} \text{ s}^{-1}$ . The resonance frequency in other fields is obtained by multiplying by the ratio of the fields. The proton resonance frequency is often used synonymously with magnetic field strength, as illustrated in Figure 3.

**Figure 3** The spin energy diagram for  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^2\text{H}$  ( $I=1$ ) as a function of field strength against energy ( $E=h\nu$ ) showing allowed transitions at 4.698 T. The energy difference between TMS and benzene protons has been exaggerated to show that, at fixed field, TMS resonates at lower frequency, while at fixed frequency, TMS resonates at higher field. The orientation of the nuclear moments and spin populations (eqn [4]) are shown on the right of the diagram.

### Natural Isotopic Abundance and Relative Sensitivity

The product of isotopic abundance and relative sensitivity determines the overall sensitivity to detection of the isotope relative to hydrogen with its 99.985% natural abundance and unit relative sensitivity. Low  $\gamma$  nuclei may be quite difficult to detect as sensitivity is proportional to  $\gamma^3$  (e.g.,  $^{57}\text{Fe}$  which is  $3 \times 10^{-5}$  times less sensitive than protons for equal numbers of nuclei). Sensitivity may be enhanced by repetitive spectral accumulation as the signal-to-noise (S/N) ratio is proportional to the square root of the number of accumulations. It requires  $10^9$  accumulations to give a  $^{57}\text{Fe}$  signal 1/50 the S/N of protons – a daunting task.

### The NMR Experiment

The essential components of an NMR spectrometer are an exceptionally stable magnet, a tunable source of RF, a high-power broadband amplifier, a high-sensitivity resonantly tuned coil surrounding the sample, and a computer for rapid data acquisition and analysis. Samples may be solids, liquids, or gases. Solutions (millimoles to moles per liter) are most widely used. There are four basic steps in an NMR experiment, as described below.

## Generation of Magnetization

When a sample is placed in a magnetic field the nuclei immediately experience a torque and begin to precess at their Larmor frequencies ( $\nu$ ) in the plane perpendicular to the magnetic field direction. The nuclear spins are oriented according to their magnetic moments. The energies of each of the  $2I + 1$  energy states are established very rapidly (the time-scale is  $1/\nu$ ). Initially, each spin state will be equally populated as the levels were degenerate without an applied field. Energy exchange with the surroundings occurs as spins flip. The spin temperature of the sample drops from infinity (equally populated states) until a Boltzmann distribution of spin populations is established at equilibrium:

$$n_i/n_0 = \exp(-\Delta E/kT) = \exp(-\hbar\gamma B_0/kT) \quad [4]$$

The approach to equilibrium is a first-order rate process and is exponential in time (cf. Newton's law of cooling). The time constant is the spin lattice relaxation time,  $T_1$  (s). The  $T_1$  of water at 200 MHz is  $\sim 15$  s. The resultant  $Z$  magnetization –  $M_z = \gamma\hbar(n_0 - n_i)$  arising from the excess population in the lower spin state – is then available for manipulation in the experiment (see Figure 3). As  $\Delta E$  for NMR is of the order of millijoules ( $\sim 2 \text{ mJ mol}^{-1}$  for protons at 4.7 T), the  $n_i/n_0$  ratio is very close to 1. However, it is this excess population in the lower state ( $n_0 - n_i \sim 3$  per  $10^5$  for protons) that generates the NMR signal. High  $\gamma$  nuclei, high fixed field, and low  $T$  all favor a larger population excess and hence higher sensitivity.

## Resonant Energy Absorption and Coherence Creation

The spins resonantly exchange energy with an oscillating RF electromagnetic field applied through a tuned coil. In pulse Fourier transform (FT) spectroscopy the RF field oscillating at  $\nu_0$  is applied as a large-amplitude, short pulse with magnetic field strength  $2\gamma B_1$ . For a typical spectrometer,  $\gamma B_1$  is of the order of 25 kHz and the pulse duration is 10  $\mu\text{s}$ . This establishes the width of the spectral range which can be excited by such a pulse at  $\sim \pm 12.5$  kHz ( $\pm \gamma B_1/2$ ).

Radiofrequency radiation induces up or down spin flips with equal probability. The number of quanta exchanged between the spins and the RF coil is enormous. Consequently, the overall behavior of the system is statistical and can be described classically. Energy is absorbed by the spins provided there is an excess population in the lower state at the time the RF is applied. This spin energy change is far too

small to influence sample temperature. A high-energy RF pulse does induce substantial heating, especially if the solvent has a high dielectric constant or the sample is highly conducting. However, the heating is electrical, not magnetic. Most importantly, a new coherent spin motion is created in the  $x$ - $y$  plane perpendicular to  $B_0$ . At equilibrium there is no  $x$ - $y$  field and so no  $x$ - $y$  magnetization. When the  $B_{1x}$  field is applied, a new coherent precessional motion occurs about it and  $x$ - $y$  magnetization is detectable (see Figure 4). The spin magnetization rotates about the combined  $B_0$  static field and the  $B_1$  RF field oscillating at  $\nu_0$ . The description of the spin motion is simplified by transformation to the rotating frame where  $B_{1x'}$  is static since the rotating frame frequency is chosen to be the RF oscillator frequency. When the RF pulse is applied the magnetization rotates about  $B_{1\text{eff}}$  for the pulse duration ( $t_p$ , s). The effective  $B_1$  field is the vector sum of  $B_{1x'}$  and  $B_{z'} = (\nu_i - \nu_0)/\gamma$ . Pulses are usually described in terms of the angle  $\theta$  through which a resonant nucleus would rotate in time  $t_p$ :

$$\theta = \gamma B_1 t_p \quad [5]$$

There are two important pulses: a  $90^\circ$  pulse, which creates maximum magnetization in the  $x$ - $y$  plane and hence maximum signal; and a  $180^\circ$  pulse, which inverts the spin population present immediately prior to the pulse (see Figure 5). The  $180^\circ$  pulse is particularly important for the accurate determination of  $T_1$  and  $T_2$ . The  $180^\circ$  pulse initiates time reversal for the  $x$ - $y$  magnetization resulting in a Hahn spin echo.

## Detection

The  $x$ - $y$  magnetization created in the excitation step is minute in absolute terms. Thus it is essential that detection is separated in either time or space from excitation. The magnetization precessing at each nuclear resonance frequency induces an alternating current in the receiver coil, which is closely wound around the sample. In Bloch's original work separate transmitter and receiver coils were mounted orthogonally to one another to provide spatial isolation of the detector from the exciting RF field, which was applied continuously. The magnetic field was swept to bring signals into resonance with the fixed frequency detector in this continuous-wave (CW) NMR experiment. In a modern pulse spectrometer, the same coil is used for excitation and detection. With pulse excitation, the detected signals are separated in time. A few microseconds after the high-power excitation has been turned off, the detector is gated on.

**Figure 4** The precessing spins and net magnetization (A) at equilibrium and (B) following a  $90^\circ$  pulse. Note the equalization of populations and generation of  $x$ - $y$  coherence. The multiple frequencies present are resolved by signal processing.

### Signal Processing

The oscillating output current from the receiver coil is amplified and mixed with the original excitation

signal. This phase-sensitive detection of the signal greatly improves the S/N ratio. The resulting signal oscillates at the difference between the transmitter frequency and the NMR resonance and is now at audiofrequencies, usually  $<20$  kHz. The multicomponent time-decaying analog signal (free induction decay, FID, or Bloch decay) is digitized into amplitude and time values in a computer (Figure 5). The process of Fourier transformation converts the FID into its frequency-equivalent spectrum. The spectrum is computed with  $NP$  points as a sum of cosine waves (real) and a sum of sine waves (imaginary) in the frequency domain, each containing  $NP/2$  points. The Nyquist requirement for a minimum of two data points to define a wave sets the frequency range. The best digital resolution – smallest resolvable frequency difference between adjacent peaks – is set by the total acquisition time,  $AT$  ( $\Delta\nu_{\min} = 1/AT$ ). This corresponds to resolving two waves whose frequencies differ by a single data point during the acquisition. There is a constant sampling time for each data point in the FID called the dwell time (DT). The finite time for signal sampling sets the highest frequency ( $f_{\max}$ ), which can be accurately represented such that  $f_{\max} = 1/2DT$ . The amplitudes of any higher frequencies (including noise!) are digitized identically to frequencies in the window and appear at  $\nu = \nu_i - \nu_{\max}$  (fold back). Ubiquitous white noise contains all possible frequencies. For realistic S/N, electronic filters with defined frequency bandwidth are essential to limit fold-back of noise from frequencies outside the spectral window.

Prior to Fourier transformation, a variety of digital weighting functions may be applied to improve the spectral appearance (Figure 5). For example, a matched filter – an exponentially decaying function with a time constant equal to the  $T_2$  decay time of the NMR signal – provides S/N optimization. Resolution enhancement is achieved at the expense of S/N by intensifying the long time tail of the FID. In addition to the standard fast FT algorithm, other data processing methods may be used for the time-to-frequency conversion. These include linear prediction – especially useful for truncated FIDs with few data points; Bayesian statistics; and maximum entropy, which are advantageous in special circumstances but with the cost of increased calculation time and memory. More elaborate acquisition schemes, which employ unequal time step functions, may be used to shorten spectral acquisition times for multidimensional experiments but at the expense of specialty data processing routines.

The absolute phase of the real and imaginary halves of the FT output cannot be established *a priori*. The experimental phase depends on the phase lags that occur inevitably in electronic circuitry. The real

**Figure 5** The basic pulsed NMR experiment showing essential processes and times. The spectrum is excited with a short resonant RF pulse of length  $t_p$ . The FID oscillates at  $\nu_1$  and decays with time constant  $T_2^*$ , which determines the linewidth and frequency following digital data acquisition and Fourier transformation. The influence of increasing pulse angle (pulse duration  $t_p$ ) is shown at lower left. For steady-state spectral acquisition, the pulse length is set for the Ernst angle ( $\cos \alpha_E = \exp(-AT/T_1)$ ). The effect of digital filtering functions applied to the FID prior to FT is shown in the lower right. The exponential filter,  $\exp(-at)$ , discriminates against high-frequency noise at the expense of line broadening; the shifted Gaussian,  $\exp(+at - bt^2)$ , generates sharp lines at the expense of the signal-to-noise ratio. (Reproduced with permission from Field LD and Sternhell S (1989) *Analytical NMR*. Chichester: Wiley. 1989; © John Wiley & Sons Ltd.)

and imaginary components must be empirically phase shifted so that the real series is in pure absorption (cosine) and the imaginary series is in pure dispersion (sine). This phase correction is optimized by maximizing the peak integral that corresponds to pure absorption. The integral for pure dispersion is zero. Furthermore, if data acquisition is delayed for a set of waves that begin with a common phase, they will dephase at a rate that is proportional to their frequency difference. Because acquisition delays appear regularly in FT-NMR experiments, a second frequency-dependent phase correction is usually required. The frequency independent phase correction is always in the range 0–360°. Much larger values may be found for the frequency-dependent correction, which is directly proportional to the acquisition time delay and the frequency offset. Finally, all the intensity information in an FID is contained in the first data point as no new magnetization is created

during acquisition. This intensity is resolved into its individual frequency contributions during the acquisition time.

## Chemical Shift

The chemical shift of a nucleus measures its immediate electromagnetic environment. The local circulation of electrons around the nucleus, induced when the sample is placed in the external magnetic field, modifies the local magnetic environment of the nucleus, resulting in the chemical shift. Its absolute magnitude is directly proportional to  $B_0$  but is only a tiny fraction of it. The range of chemical shifts varies enormously from  $\sim 1$  ppm for  $^3\text{He}$  through 20 ppm for  $^1\text{H}$  and  $^2\text{H}$  (isotopes have the same shifts) and 300–1500 ppm for main group elements  $^{13}\text{C}$ ,  $^{11}\text{B}$ ,  $^{15}\text{N}$ , and  $^{19}\text{F}$  to over 10 000 ppm for transition metals such as  $^{59}\text{Co}$  and  $^{119}\text{Sn}$  and the rare-earth elements.

Detailed correlations of chemical shifts with functional groups may be found in articles dealing with particular nuclei.

The chemical shift literature represents an interesting blend of philosophical approaches. Since frequencies are measured with great accuracy and linewidths are narrow in solution, chemical shifts are exquisitely sensitive reporters of local molecular environment. For example, the relative stereochemistry of the methyl groups, separated by up to five monomer units (13 bonds) along the chain, in polypropylene can be distinguished by carbon NMR (see Figure 6).

Empirical group additivity rules have proved to be effective predictors of chemical shifts for many classes of compounds. Extensive spectral tables are available in many texts and are very useful for structure identification provided representative model compounds are available (e.g., tripeptides for proteins, additivity rules for  $^{13}\text{C}$  in organics). The *ad hoc* explanations that accompany such assignments often have little basis in reality. For accurate interpretation of chemical shift trends, the individual components of the chemical shift tensor must be considered. Molecular orbital calculations on systems of up to

50 first-row atoms may now be done with close to experimental accuracy.

Small solvent and related effects may be useful for resolving spectral overlap, particularly when magnetically anisotropic solvents are used such as pyridine and acetone. Common NMR solvents are listed in Table 3. Anisotropic circulation of electrons in molecular groups, e.g., aromatic rings, ring currents, and shift reagents, may induce chemical shifts. The relative orientation and distance to the anisotropic group control the magnitude. This anisotropy induced shift is most important for protons as its magnitude is independent of the nucleus observed.

Chemical shift is measured on a ppm scale relative to a standard of known frequency. TMS is the practical frequency standard for  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{29}\text{Si}$ . In principle, the absolute frequency reference is the electron-free nucleus. For theoretical work, the shift of the neutral diamagnetic atom is used as it may be calculated accurately. Alternatively, the absolute scale may be established independently of the NMR experiment from the rotational splitting constant measured by microwave spectroscopy on a reference gas, e.g., CO for  $^{13}\text{C}$  and  $^{17}\text{O}$ . In Figure 7, the chemical shift/shielding scale for  $^{13}\text{C}$  is shown together with the terms used to describe changes in shift.

Chemical shift is a tensor quantity whose three principal elements can be determined for molecules with a small number of unique resonances from the turning points of the shielding pattern in solid samples. Multidimensional methods are required for resolution in more elaborate spectra. The isotropic chemical shift observed in solution is the simple average of the principal components measured in the solid. Thus,  $\sigma_{\text{iso}} = (\sigma_{xx} + \sigma_{yy} + \sigma_{zz})/3$ . Chemical shift is a highly localized interaction. Shielding is induced by electron circulation in the plane perpendicular to the applied magnetic field direction and so changes with molecular orientation. The original Ramsey perturbation theory of chemical shift defines the essential chemical shift components:

$$\begin{aligned} \sigma_{zz} = \sigma_{zz}^{\text{d}} + \sigma_{zz}^{\text{p}} = & \frac{e^2}{2mc^2} \left\langle 0 \left| \frac{x^2 + y^2}{r^3} \right| 0 \right\rangle \\ & + \left( \frac{eh}{2mc} \right)^2 \sum_n \left\{ \frac{\langle 0 | L_z | n \rangle \langle n | 2L_z / r^3 | 0 \rangle}{E_n - E_0} \right. \\ & \left. + \frac{\langle 0 | 2L_z / r^3 | n \rangle \langle n | L_z | 0 \rangle}{E_n - E_0} \right\} \end{aligned} \quad [6]$$

The first term is the diamagnetic contribution ( $\sigma^{\text{d}}$ , upfield, more shielded), which arises predominantly from the induced circulation of the inner-shell electrons generating a magnetic field opposed to the applied field. It increases monotonically with atomic

<sup>a</sup>The <sup>1</sup>H spectra of the residual protons and <sup>13</sup>C spectra were obtained on a Varian Gemini 200 spectrometer at 295 K. The samples for the <sup>1</sup>H and <sup>13</sup>C spectra contain a maximum of 0.05 and 1.0% TMS (v/v), respectively. Since deuterium has a spin of 1, triplets arising from coupling to deuterium have the intensity ratio of 1:1:1. (m) denotes a broad peak with some fine structure. It should be noted that the chemical shifts, in particular, can be dependent on solute, concentration, and temperature.

<sup>b</sup>Approximate values only: may vary with pH, concentration, and temperature.

<sup>c</sup>Melting and boiling points are those of the corresponding compound (except for D<sub>2</sub>O). These temperature limits can be used as a guide to determine the useful liquid range of the solvents. Courtesy of Cambridge Isotope Labs, Andover, MA, USA, used by permission.

**Figure 7** The carbon chemical shift scale. (A) The experimental shift ( $\delta_{\text{TMS}} = 0.0$ ) and theoretical shielding ( $\sigma = 0$ ) scales for standard reference compounds. (B) The theoretical shielding scale for atomic carbon together with common shielding synonyms.

number. The second, paramagnetic, term is dominant for atoms containing electrons with orbital angular momentum (p, d, f, etc., but not s). It determines the induced paramagnetic circulation of electrons as the orbital angular momentum in the atom is quenched on bond formation. Linear molecules have particularly large chemical shift anisotropy, as only diamagnetic shielding is possible when the field and molecular axes are collinear. In the perpendicular orientation, large paramagnetic contributions are the rule.

There are three essential components of eqn [6]. The  $r^{-3}$  distance term accounts for the common and generally valid correlation of chemical shift with charge density (e.g., 160 ppm/e for  $^{13}\text{C}$  in  $\pi$  systems). However, other terms can dramatically alter this simple correlation. For example, cations are known that appear upfield of anions, contradicting the simple charge prediction of cations at low field. The  $\langle 0|L_z|n\rangle$  orbital angular momentum terms select for orbital angular momentum contributions such as  $\pi_x \rightarrow \pi_y^*$ . In symmetric situations, this term can go to zero as it does in linear molecules leaving only the diamagnetic shielding. Finally, there is the excitation energy for electron promotion ( $E_n - E_0$ ), a consequence of the Ramsey perturbation treatment. This is best illustrated with transition metal shifts where a linear relationship is found between the 'forbidden'  $t_{2g} \rightarrow e_g$  optical transition energy and the chemical shift. Note that this energy term is generally not the HOMO-LUMO gap (HOMO is the acronym for highest occupied molecular orbital, and LUMO the acronym for lowest unoccupied molecular orbital). Induced electron circulation generates the chemical shift and so the perturbation terms must represent an electronic excitation that changes the electron angular momentum in direct proportion to the applied magnetic field.

Proton chemical shifts of O-H and N-H groups are strongly dependent on solvent and temperature because of changes in hydrogen bonding. The shift difference between alkyl and hydroxyl protons is used as a thermometer (methanol below room temperature, ethylene glycol above). The  $^{59}\text{Co}$  shift in  $\text{K}_3\text{Co}(\text{CN})_6$  is an even more sensitive thermometer. For solids, the  $^{207}\text{Pb}$  shift in lead nitrate is the standard thermometer.

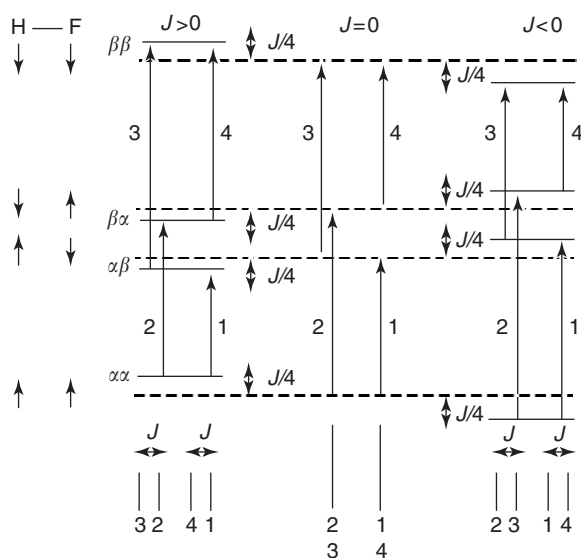

In systems with unpaired electrons (e.g., metals, radicals, paramagnetic transition metal complexes), a much larger range of chemical shifts is possible. Now the major magnetic interaction is between the nucleus of interest and the unpaired electron(s). The observed shift depends on the excess electron spin population and the coupling constant to the nucleus. The induced contact shifts or Knight shifts (in metals and conductors) often exceed 1000 ppm.

## Spin-Spin Coupling

The presence of coupling between a pair of nuclei establishes molecular connectivity usually over one, two, or three bonds and is a very powerful tool for molecular structure determination. The internuclear coupling constant  $J$  is transmitted by the bonding electrons. Coupling through as many as 10 bonds has been detected in delocalized  $\pi$  systems. By tracing coupling paths (e.g., in COSY spectra), molecular connectivity can be established uniquely and unequivocally. In a sophisticated experiment (INADEQUATE), one-bond  $^{13}\text{C}$ - $^{13}\text{C}$  coupling in natural abundance is used to trace carbon connectivity in organic molecules. The magnitude of the three-bond coupling constant often provides stereochemical information through the Karplus relationship relating  $J$  to the internuclear dihedral angle (see Figure 8).

**Figure 8** The Karplus relationship for three-bond proton-proton coupling relating dihedral angle and  $J$ . (Adapted from Campbell ID and Dwek RA (1984) *Biological Spectroscopy*. Menlo Park, CA: Benjamin/Cummings.)

**Figure 9** Energy diagram and spectrum for a two-spin coupled system showing allowed transitions and effect of  $J$  coupling. The energy scale is severely distorted as the energy gaps are in the megahertz range and the coupling energies are in hertz.

The coupling constant measures the energy of interaction between two nuclei and is independent of the applied magnetic field. When the spin dipoles are opposed, a positive coupling constant denotes that the energy is lowered, and vice versa. Positive coupling is the norm, but negative coupling is routinely found between protons in  $\text{CH}_2$  groups. For two spins, such as molecular HF, there are four possible spin combinations each with a specified energy – both up ( $\alpha\alpha$ ), both down ( $\beta\beta$ ), and two with one up and one down ( $\alpha\beta$  and  $\beta\alpha$ ) (see Figure 9).

				1		1					
				1		2		1

1	10	45	120	210	252		210	120	45	10	1

**Figure 10** Pascal's triangle.

The four-line spectrum arises from the four allowed transitions in which there is a single spin flip. They have equal probability and so equal intensity. In the absence of coupling the pair of transitions for a given nucleus is of equal energy and appears as single lines. When the nuclei are coupled, the transitions differ in energy by  $J$  Hz. The splitting is the same for each nucleus. If a nucleus is coupled to  $n$  other spin  $1/2$  nuclei, there are  $2^n$  possible lines for the observed nucleus. For  $n$  nuclei coupled with equal  $J$  (e.g., the three hydrogens of a methyl group) to the observed nucleus, the peak multiplicity is  $2nI + 1$ . They have binomial intensities corresponding to the statistical probability of the spins having a given total spin quantum number – the familiar Pascal's triangle shown in Figure 10. Splitting patterns are multiplicative as shown by the  $\text{CH}_2$  group of dry ethanol which is a doublet of quartets (see Figure 1).

Spectral splitting patterns reveal the quantum character of the nuclear coupling interactions. Two energy levels of a coupled spin system may not be closer in energy than the  $J$  coupling between the nuclei. The spectral consequences of these quantum effects include distorted line intensities (haystacking), line spacings that no longer equal  $J$ , and the appearance of a finite number of extra lines and in some cases fewer lines than predicted by first-order rules. The single line spectrum observed for benzene is one such example. Even though each proton is coupled to the five other protons on the ring, no splitting is observed. Equivalent nuclei do not split each other. The proton spectra of 1,1-difluoromethane and 1,1-difluoroethene are dramatically different (see Figure 11). In  $\text{CH}_2\text{F}_2$ , the pairs of protons are indistinguishable and the fluorines are split into a simple triplet. For  $\text{CH}_2\text{CF}_2$  the protons are magnetically nonequivalent. They are distinguished by their different couplings to the *cis* and *trans* orientated fluorines. Despite the complexity of the pattern, the spectral symmetry reflects the symmetry in the

**Figure 11** 60 MHz  $^1\text{H}$  NMR spectra of (A)  $\text{CH}_2\text{F}_2$  and (B)  $\text{CH}_2=\text{CF}_2$  showing the effect of magnetic nonequivalence. The pattern is identical in the  $^{19}\text{F}$  spectrum and is unchanged at higher  $B_0$ . These spectra were obtained by sweeping the field at constant frequency as shown by the ringing distortion. (Reproduced with permission from Becker ED (1969) *High Resolution NMR*. Orlando, FL: Academic Press.)

coupled groups. Related effects are commonly observed in equivalently *ortho* and *para* disubstituted benzenes, and in  $\text{X}-\text{CH}_2\text{CH}_2$  systems. All these spectra may be computed with high accuracy in programs such as LAOCOON. The input information is the chemical shifts and coupling constants. The line positions and intensities are then computed in a quantum mechanical calculation without approximation.

The Fermi contact interaction is the major mechanism for  $J$  coupling. It is governed by the electron density at the nucleus ( $S_i$ ) and the nuclear gyromagnetic ratio according to the expression

$$J(\text{A}, \text{X}) = \left(\frac{\mu_0}{3\pi}\right)^2 \beta^2 h \gamma_{\text{A}} \gamma_{\text{X}} |S_{\text{A}}|^2 |S_{\text{X}}|^2 P_{\text{AX}}^2 / (E_{\text{T}} - E_{\text{S}}) \quad [7]$$

$P_{\text{AX}}$  is the A–X bond order and  $E_{\text{T}} - E_{\text{S}}$  the electronic excitation energy for triplet formation. The magnitude of the  $^{13}\text{C}-^1\text{H}$  one-bond  $J$  value increases with  $S$  character at carbon ( $J_{\text{C-H}}$  ethane = 125 Hz, acetylene = 210 Hz). Isotopic substitution is generally a minor perturbation on the electronic coupling and the observed  $J$  coupling is proportional to  $\gamma$ .

For example,

$$J_{\text{X-H}} = \frac{\gamma_{\text{H}}}{\gamma_{\text{D}}} J_{\text{X-D}} \quad [8]$$

Some notable exceptions to the generalization have been observed in systems with three hydrogen ligands on a common metal center where tunneling dominates the coupling surface. In its full form  $J$  is also a tensor quantity and additional orientation dependent contributions involving orbital and spin–dipolar coupling interactions have been established, especially with multielectron atoms.

In orientated samples (e.g., liquid crystals, solids), the through-space dipole–dipole coupling is combined with the  $J$  coupling. Because the dipolar coupling is often in the kilohertz range,  $J$  coupling is usually too small to detect in anything except fluid media. Residual dipole couplings measured in slightly oriented fluid medium find use in structure determination.

## Relaxation and Molecular Rotational Dynamics

Without relaxation, NMR spectra would be unobservable! NMR relaxation is a major tool for the determination of molecular dynamics on the microsecond to picosecond timescale. The nucleus is the ultimate molecular level sensor and is sensitive to motion on the scale of molecular fragments and small groups. The nuclear relaxation probe is most effective on timescales comparable to the inverse of the resonance frequency ( $1/\omega_0$ ), i.e., in the nanosecond to picosecond regime, which occurs most frequently in fluid solution. The energy absorbed by the spins from the RF excitation must be dissipated to the surroundings prior to repetition of the experiment. If not, the populations of each level will become equal (saturation) and there is no net magnetization to detect. Nuclei with  $I = 1/2$  are unaffected by electric fields and are only magnetically coupled to their surroundings. Thus, the broadening observed in electronic spectra from collisional processes is absent. As molecular magnetism is weak, spin relaxation times are usually long, ranging from milliseconds to kiloseconds. Relaxation is assumed to be a random dissipative process and follows an exponential decay with time constant  $T_1$ . Just as for spin excitation, the dissipative relaxation process requires an oscillatory magnetic field at the resonance frequency (i.e., an energy match). A change in nuclear spin state is limited to unit change in resonant spin quantum energy and requires a change in angular momentum by one unit. The nuclear spin quantum is the smallest quantum of energy. The relaxation rate  $R_1 = 1/T_1$  is specified by the expression  $R_1 = CB^2J(\omega)$  where  $C$  is a constant,  $B$  is the mean local magnetic field at the nucleus, and  $J(\omega)$  is the spectral density

**Table 4** Equations for spin–lattice relaxation rates,  $R_1$ , of nucleus A, for various mechanisms in the extreme narrowing approximation

Mechanism	$R_1$	Notes	Diagnostic	Examples
DD(intra) (homo)	$\left(\frac{\mu_o}{4\pi}\right)^2 \frac{3}{2} \gamma_A^2 h^2 \tau_c / r^6$	For a single pair of spin-1/2 nuclei of separation $r$	Overhauser effect	Protons at low conc. In deuterated solvent
DD(intra) (hetero)	$\left(\frac{\mu_o}{4\pi}\right)^2 \gamma_A^2 \gamma_X^2 h^2 \tau_c / r^6$	For a single pair of spin-1/2 nuclei AX of separation $r$	Overhauser effect	$^{13}\text{C}$ in cholesterol, most protonated carbons
DD(inter) (hetero)	$\left(\frac{\mu_o}{4\pi}\right)^2 \frac{2}{15} N_X \gamma_A^2 \gamma_X^2 h^2 / D a$	For paramagnetic relaxation of a spin-1/2 nucleus by particle X, when X has unpaired spins	Proportional to $N_X$	Relaxation of water protons by dissolved $\text{O}_2$ or $\text{Cr}(\text{AcAc})_3$
Unpaired electron (intra) (dipolar)	$\left(\frac{\mu_o}{4\pi}\right)^2 \frac{4}{3} \gamma_A^2 \gamma_e^2 h^2 S(S+1) \tau_c / r$	For relaxation by unpaired electrons of total spin $S$ at distance $r$	EPR	Most radicals: relaxation agent $\text{Gd}(\text{DPM})_3$
Spin rotation	$2I_r k T C^2 \tau_{sr} / h^2$	For isotropic molecular moment of inertia ( $I_r$ )	Proportional to $T$	Gaseous $\text{CS}_2$ : most gases
CSA	$\frac{2}{15} \gamma_A^2 B_0^2 \Delta \sigma^2 \tau_c$	For nuclei with large CSA	Proportional to $B_0^2$	Quaternary $^{13}\text{C}$ and $^{31}\text{P}$ in phosphates at high field $^{195}\text{Pt}$ in square planar complexes
Scalar coupling	$\frac{8\pi^2 J_{AX}^2 I_X(I_X+1) \tau_{sc}}{3[1 + (v_X - v_A)^2 \tau_{sc}^2]}$	Relaxation by coupling to spin, X, of quantum number $I_X$ . Requires $\gamma_A \approx \gamma_X$	Inversely proportional to $B_0^2$	$^{13}\text{C}$ in cyclohexylbromide 'Unique' to $^{13}\text{C}$ – $^{79}\text{Br}$
Quadrupole	$(eqQ/h)^2 \tau_c$	Relaxation of quadrupole by electric field gradient	$I > 1/2$	Almost all quadrupolar nuclei $^{17}\text{O}$ in compounds; halides except $^{19}\text{F}$
Raman scattering	$\frac{81\pi}{10\omega_D} (F_2)^2 \left(\frac{T}{\theta_D}\right)^2$	Relaxation of high Z spin 1/2 nuclei in solids	Proportional to $T^2$ Independent of $B_0$	$^{207}\text{Pb}$ in lead salts

AcAc, acetylacetonate; EPR, electron paramagnetic resonance; DPM, dipivaloylmethane;  $\tau_c$ , Correlation time for molecular tumbling;  $N_X$ , concentration of spins X (per unit volume);  $D$ , mutual translational self-diffusion coefficient of the molecules containing A and X;  $a$ , distance of closest approach of A and X;  $\gamma_e$ , magnetogyric ratio for the electron;  $C$ , spin–rotation interaction constant (assumed to be isotropic);  $\Delta\sigma$ , shielding anisotropy ( $\sigma_{\parallel} - \sigma_{\perp}$ );  $\omega_D$ , Debye frequency;  $\theta_D$ , the corresponding Debye temperature;  $F_2$ , spin–phonon coupling constant.

function. The major local fields contributing to relaxation are shown in Table 4, together with representative examples and a method for confirming each contribution. For molecules in solution with  $I = 1/2$ ,  $T_1$  values are usually in the range 0.1–10 s. In the presence of unpaired electrons, and for quadrupolar nuclei, values of milliseconds to microseconds are found. For immobilized systems, such as solids, and spins isolated from other magnets, times of minutes to days have been measured.

The probability of finding the molecular fragment oscillating at the resonance frequency  $\omega$  is determined by  $J(\omega)$ . The oscillatory motion arises from random Brownian motion. The frequency distribution of Brownian motion is Gaussian and may cover

12 orders of magnitude for a mobile liquid:

$$J(\omega) = \int_{-\infty}^{\infty} G(\tau) e^{i\omega\tau} d\tau \quad [9]$$

with

$$G(\tau) = \langle f(t+\tau)^* f(t) \rangle \quad [10]$$

being the autocorrelation function. It measures the persistence of local fluctuations,  $f(t)$ , and is assumed to decay exponentially with a time constant  $\tau_c$  known as the correlation time. This gives

$$J(\omega) = \frac{2\tau_c}{1 + \omega^2 \tau_c^2} \quad [11]$$

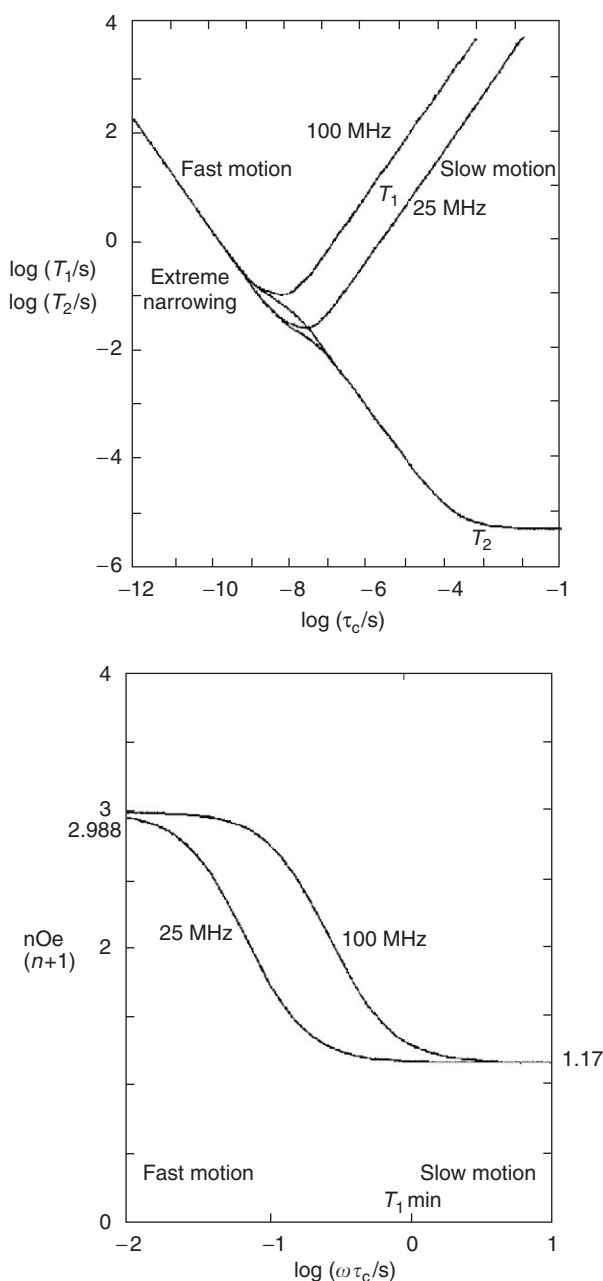

The correlation time can be interpreted as the mean time for the molecular fragment to rotate through 1 radian. Alternatively, it is the inflexion point on the Gaussian distribution function describing the motion. For moderate molecular weight, approximately spherical molecules of volume  $V$ , in a solvent of viscosity  $\eta$ , the Stokes–Einstein relationship  $\tau_c = V\eta/kT$  applies surprisingly well. For small molecules, a semiempirical correction factor may also be needed when dealing with solvents whose volume is comparable to the solute. For anisotropically rotating groups (e.g., methyl groups, side chains in polymers, and substituted phenyl groups rotating about their C2 axis) a more detailed motional analysis is required.

The relationship between the correlation time and relaxation time is shown in the log–log plot of **Figure 12**. On the short correlation time, fast motion side of the diagram where  $\omega\tau_c \ll 1$ , an increase in fluidity makes relaxation less efficient, resulting in a longer  $T_1$ . This is known as the ‘extreme narrowing’ regime and  $T_1$  is inversely proportional to  $\tau_c$ . In this regime, fast molecular motion averages dipole–dipole coupling and chemical shift anisotropy to zero, giving narrow spectral lines. On the slow motion side of the relaxation maximum,  $\omega\tau_c \gg 1$ , increased motion generates faster relaxation and  $T_1$  is proportional to  $\tau_c$ . On the slow motion side molecular systems are usually solids or high molecular mass polymers and broad lines are the rule. A treatment in terms of random Brownian motion is often too simplistic for such materials. A broad distribution of correlation times and differential segmental motion descriptions are usually needed to account for the relaxation behavior. In solids it is not uncommon to find that nuclei in all molecular fragments relax with a single correlation time, which corresponds to the motion of the mobile portion of the molecule such as a rotating methyl group. The maximum relaxation rate occurs when  $\omega\tau_c = 1$  and  $R_1 = CB^2/2\omega_0$ . Relaxation efficiency decreases with increasing resonance frequency as  $B^2$  is usually independent of field. Chemical shift anisotropy relaxation is an exception as the magnetic interaction increases as the square of the magnetic field.

NMR relaxation may be used to probe molecular motion in the kilohertz range, using the relaxation time in the rotating frame,  $T_{1\rho}$ . Here the relaxation is determined in the presence of the RF magnetic field. In this case there is a nonzero  $x$ – $y$  field given by the amplitude of the RF field ( $\gamma B_1$ ). The relaxation rate maximum ( $1/T_{1\rho}$ ) occurs at a frequency  $\omega = \gamma B_1/\pi$ .

The  $T_1$  relaxation time is best measured in an inversion–recovery pulse experiment. A  $180^\circ$  pulse is applied to the signal of interest that inverts the spin

**Figure 12** The relationship between carbon  $T_1$  and  $T_2$ , relaxation times, and the correlation time for rotational diffusion,  $\tau_c$ , for  $^{13}\text{C}$  spin being dipolar relaxed by a bonded proton. Relaxation is less efficient at higher  $B_0$  field (indicated by carbon resonance frequencies). Curves for other relaxation mechanisms may be generated by appropriate scaling. The lower curve shows the nOe in the region of the  $T_1$  minimum where  $\omega\tau_c \sim 1$  and differential cross-relaxation is effective. Curves for other dipolar pairs may be constructed by scaling the limiting nOes according to eqn [15].

population.  $z$ -Magnetization is perturbed as far as possible from equilibrium. A composite pulse is recommended to ensure full inversion and that there is no residual  $x$ – $y$  magnetization. A variable time delay

is introduced during which the  $z$  magnetization relaxes back toward equilibrium. A  $90^\circ$  pulse is then used to sample the residual  $z$  magnetization. The  $T_1$  is determined by fitting the recovery curve

$$M(t) = M(\infty)[1 - 2 \exp(-t/T_1)] \quad [12]$$

where  $t$  is the variable time delay and  $M(t)$  is the magnetization at time  $t$ . It is necessary to wait at least  $5 \times T_1$  between  $180^\circ$  pulses to ensure that spin equilibrium is restored and  $M(\infty)$  is at its maximum value. This is a general requirement for repetition of experiments. It applies to any experiment that requires equilibrium spin populations initially.

## Dynamics, Lineshapes, and Homogeneity

Frequency and time are inversely correlated in any NMR experiment. In order to observe an interaction in the frequency spectrum, the nuclei must experience that interaction for a time that is long with respect to the inverse of the interaction frequency. Fast processes result in frequency averaging. Examples include isotropic molecular tumbling in solution which averages dipolar coupling to zero with the resulting narrow lines; magic angle spinning in solid-state NMR to remove chemical shift anisotropy; and molecular dynamics which provides conformationally averaged coupling constants.

A solution NMR peak commonly has a Lorentzian shape. A Lorentzian line in the frequency domain results from a first-order exponential decay process with a time constant,  $T_2$ . It is specified by the lineshape function,  $f(\nu)$ , where

$$f(\nu) = \frac{2T_2}{1 + 4\pi^2 T_2^2 (\nu_i - \nu)^2} \quad [13]$$

Here  $T_2$  (s) is the spin-spin relaxation time.  $T_2$  can be estimated from the full linewidth at half-height  $\Delta\nu = 1/\pi T_2$ . For accurate work  $T_2$  is determined in a spin echo experiment, which cancels linewidth contributions from magnetic field inhomogeneities. In a highly homogeneous magnet the linewidths of small molecules, such as TMS, may be as narrow as 0.1 Hz.

The linewidth specification for commercial solution spectrometers is commonly  $\leq 0.3$  Hz across a 5 mm sample, independent of absolute magnetic field. Note that this requires a magnetic field that is stable (see eqn [1]), and uniform (homogeneous) to better than 1 part in  $10^9$  across the sample – a remarkable engineering feat. The sharpest line in a spectrum provides a measure of the actual instrument homogeneity. In practice, ideal Lorentzian lineshapes are

common, while Gaussian and other more complex shapes are also found in poorly shimmed (inhomogeneous) magnets. Deviation from magnet ideality contributes to the shape of all peaks in the spectrum.

Magnetic interactions also shorten spin lifetimes and contribute to line broadening. Paramagnetic impurities such as ferromagnetic particulates, dissolved oxygen, and transition metals are a common source of broadening. For large molecules – greater than 10 kDa – and in highly viscous media dipolar interactions between neighboring nuclei cause broadening when the slow tumbling in solution is insufficient to average the dipolar interaction.

## Chemical Exchange and NMR Timescales

The intrinsic linewidth of a peak measures the lifetime of a spin in a given configuration. Lifetimes may depend on chemical processes such as the proton exchange between water and the ethanol OH shown in Figure 1. In such cases, an order of magnitude estimate of the kinetics of the exchange process can be made using the uncertainty principle

$$\Delta E \Delta t \sim h/2\pi \quad \text{or} \quad \Delta\nu \Delta t \sim 1 \quad [14]$$

For the OH exchange,  $\Delta\nu_{1/2}$  for water was measured to be 25 Hz and the exchange rate is  $\sim 75 \text{ s}^{-1}$  for this OH group. The hydroxyl proton line of ethanol is significantly narrower. This is because the lifetime of the proton bound to alcohol is longer than its lifetime when bound to water, as required for chemical equilibrium. The exchange lifetimes are directly proportional to the population at each site. If the rate is very much faster than the chemical shift difference in hertz, then a single sharp line is observed at the population-weighted average shift. Accurate kinetics may be determined from exact lineshape calculations. NMR has a unique ability to reveal ‘invisible’ chemically degenerate processes. Examples include proton exchange rates in water, bond rotations, and ligand interchanges in complexes. Intramolecular processes may be distinguished from intermolecular processes by the presence of averaged coupling constants. Chemical kinetics may also be measured by saturation transfer. Spin population information is transferred from site to site by chemical exchange. Saturation at one site will appear at a new site provided exchange is faster than  $T_1$  relaxation.

## Diffusion

Molecular diffusion (and flow) may be measured in the presence of magnetic field gradients using the Stejskal–Tanner spin-echo technique. Diffusion in a gradient dephases the magnetization between pulses. The technique may be incorporated into

multidimensional pulse sequences, e.g., DOSY, to discriminate signals in mixtures on the basis of diffusion coefficient/molecular size. Combined nOe and diffusion experiments provide information on binding small molecules to large molecules, which finds application in drug discovery.

### Sample Spinning, Field/Frequency Lock, and Field Gradients

Sample spinning about the  $z$ -axis averages the static  $x$ - $y$  magnet inhomogeneities. In poorly shimmed magnets, spinning side-bands are found separated from the main peak at multiples of the spinning frequency. Ideal lineshapes may be recovered by computer deconvolution to remove the effects of magnetic inhomogeneity if an ideal reference line is available. Most spectrometers also employ a field/frequency lock to overcome effects of drifting fields. A signal from a reference – commonly deuterium in a deuterated solvent – is detected in dispersion mode. Magnet drift produces a signal which is used in a feedback loop to compensate for the drifting field.

Pulsed field gradients are used to shorten experimental times in multidimensional NMR by removing the  $T_2$  limit on pulse repetition times. As spin frequency is proportional to the applied field, field gradients are used to discriminate between multiple quantum spin orders in multipulse experiments, e.g., DQ filtered COSY experiments that discriminate against the strong diagonal signals arising from single quantum excitation.

### Double Resonance and Decoupling

Coupled spectra contain a wealth of bonding information. However, in many situations, the information content is more readily interpreted if this spectral complexity is removed by decoupling. Decoupling is achieved by applying a second RF field at the resonance of the nucleus whose coupling is to be removed. The decoupling may be selective, involving a single group or even a single line within a group, or may be broadbanded and cover the full spectrum. The amplitude of the decoupler field must be larger than the coupling constant to the nucleus to be decoupled. If lower fields are used, or the frequency is offset, additional lines and line broadening may be observed (see **Figure 13**). A low-power RF pulse applied selectively may be used for specific inversion of populations.

Broadband proton decoupling is used routinely when carbon spectra are obtained. For complete decoupling, the observed spin and the decoupled spin must be orthogonal.  $J$  coupling is a scalar, and the

coupling contribution to the energy is determined by the dot product of the spin angular momenta  $\mathbf{J} \cdot \mathbf{I} \cdot \mathbf{S}$ . Alternatively, but not equivalently, spins may be decoupled by randomizing their orientation relative to one another in a time which is fast with respect to  $1/J$ . Many processes randomize spin orientation: rapid  $T_1$  relaxation which decouples quadrupolar nuclei, chemical exchange which breaks bonds, and by noise decoupling in which the frequency of the irradiation is rapidly and randomly varied around the resonance frequencies to average  $\mathbf{J} \cdot \mathbf{I} \cdot \mathbf{S}$  to zero. More sophisticated multiple pulse versions for broadband decoupling exist, which minimize the power levels required (e.g., WALTZ, GARP, MLEV 17, etc.).

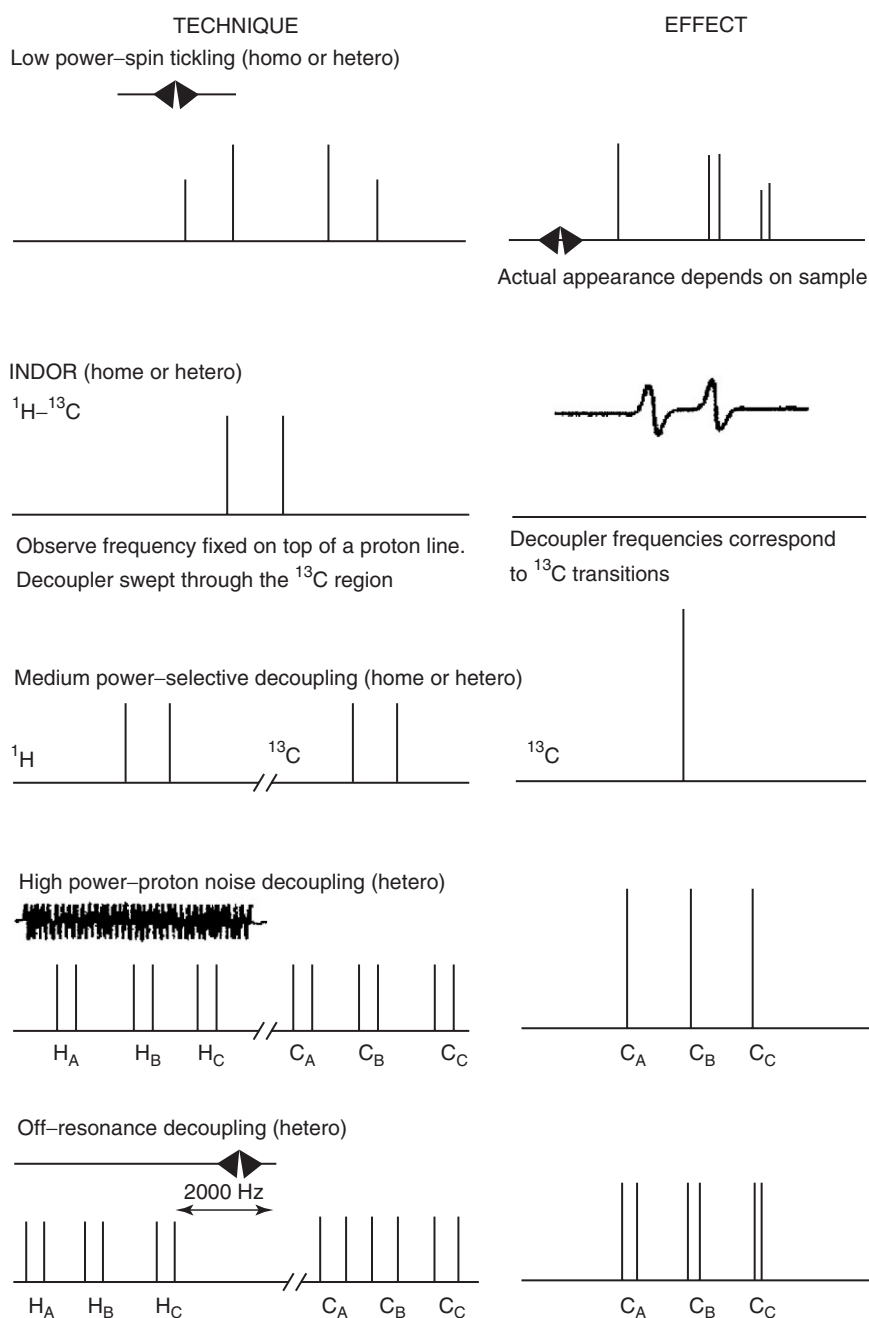

Since an additional oscillating magnetic field is present while the decoupler is on, the irradiated spins have new coherent motions and new energy states. The decoupler is also an energy source and so spin populations are perturbed. While the new energy states and line positions are generated immediately, spin population changes still require times comparable to  $T_1$  and  $T_{1\rho}$ . The most important population changes occur in dipolar coupled systems and give rise to the nuclear Overhauser effect (nOe). Pulse sequences have been developed to exploit the time differentials to obtain decoupled spectra without nOe for spin counting or coupled spectra with nOe to enhance sensitivity.

### Nuclear Overhauser Effect

The dipolar relaxation mechanism is unique because the dipolar coupling interaction contains two spin terms involving mutual spin flips – zero quantum  $\uparrow\downarrow \rightleftharpoons \downarrow\uparrow$  and double quantum  $\uparrow\uparrow \rightleftharpoons \downarrow\downarrow$  transitions. All other relaxation processes are limited to single spin interchange. While the decoupler is on, the spin population differences between the levels irradiated are equalized as the rate of energy input from the decoupler greatly exceeds the outflow by relaxation. In dipolar coupled systems, the availability of double and zero quantum relaxation pathways (cross-relaxation) produces non-Boltzmann spin populations in the energy levels of the observed nucleus. These perturbed populations are measured as the nuclear Overhauser effect (nOe) effect ( $\eta$ ). The relationship is

$$\eta = \frac{R_c}{R_1 + R_x} \frac{\gamma_S}{\gamma_I} = \frac{M_{\text{irr}}}{M_0} - 1 \quad [15]$$

where  $R_c$  is the cross-relaxation rate between spins  $I$  and  $S$ .  $I$  is the observed and  $S$  the irradiated nucleus.  $R_1$  is the dipolar relaxation rate and  $R_x$  is the relaxation rate for all other relaxations (**Table 4**).  $M_{\text{irr}}$  and  $M_0$  are the integrated intensity of  $I$  in the presence

**Figure 13** Summary of double resonance techniques and their influence on the spectrum. (Reproduced with permission from Abraham RJ, Fisher J, and Loftus P (1988) *Introduction to NMR Spectroscopy*. Chichester: Wiley; © Wiley.)

and absence of irradiation of  $S$ . For extreme narrowing when zero, single, and double quantum dipolar relaxations contribute,  $R_c/R_1 = 1/2$ . In the slow motion limit when only zero quantum terms apply,  $R_c/R_1 = -1$ . The  $n\text{Oe}$  dependence on correlation time was illustrated in Figure 12. The detection of an  $n\text{Oe}$  is diagnostic of dipolar relaxation and usually implies that nuclei are within 0.5 nm of each other. The relative rate of alternative relaxation processes sets the distance cutoff. If differential  $n\text{Oe}$  values or

the rate of change of  $n\text{Oe}$  can be measured, relative distance information may be obtained. A full relaxation analysis is necessary for accurate distance measurement.

### Polarization Transfer

The ability to transfer population information via dipolar coupling and double resonance is particularly useful for enhancing the detectability of insensitive

nuclei. The low-sensitivity nuclear resonance is irradiated, the information transferred via the coupling, and the sensitive nucleus is detected. Over 10% of the total spins in gaseous helium and xenon can be polarized through dipole coupling with rubidium atoms that have been optically pumped with a laser. The spin relaxation time for rare gases at low pressure can be of the order of hours. This enormous signal enhancement and the great sensitivity of xenon chemical shifts to local environment has been used to probe surfaces and also for MRI. Remarkable polarization transfers approaching 50% have been achieved by microwave irradiation of organic radicals. This technique allowed detection of  $^{13}\text{C}$  labeled urea by MRI.

## Quantitative Analysis

At first sight, quantitative analysis by NMR might be expected to be highly accurate and broadly applicable since the 'extinction coefficient' for NMR is unity. In practice, it is found that the best accuracy achievable in extensive studies of proton NMR of known mixtures is  $\pm 1\%$ . Results at this level of accuracy require very careful attention to the selection of the experimental parameters such as pulse width, pulse repetition time, and nOe effects and the availability of calibration mixtures. For  $^{13}\text{C}$  analysis the accuracy is commonly poorer,  $\sim 1\text{--}5\%$ , because of the reduced S/N ratio and the variation of nOe contributions with molecular structure and field strength. Errors of  $\pm 10\%$  or more are not uncommon in quantitative analyses especially when conducted by inexperienced operators. In proton NMR, linewidth variation is an underappreciated issue. Careful control of experimental parameters, and the use of calibration mixtures are minimum requirements for accurate analyses and accuracies of  $\pm 0.5\%$  have been achieved by experts.

A fundamental characteristic of Lorentzian lines is their slow return to baseline as a function of frequency offset from resonance. Thus, broad lines such as the OH peak in ethanol, and especially intense solvent peaks, contribute intensity throughout a spectrum. The decay of the signal to the baseline is linearly dependent on the linewidth at half-height. For example, to obtain an integral corresponding to 99.0% of the total peak intensity of a Lorentzian line, one must integrate over 63.6 linewidths. This value is obtained from  $f(v)$  – the Lorentzian function – eqn [13]:

$$\text{Int} = K \int_{-v}^v f(v) dv \quad [16]$$

where  $\pm v$  are the integration limits and  $K$  is the instrument response factor. If the frequency scale is normalized in units of the full-peak linewidth at half-height, the integral takes the form

$$\text{Int} = 2K \int_0^{x_L} f'(x) dx = 2(K/\pi) \arctan(x_L) \quad [17]$$

where  $x_L$  is the integration cutoff in units of linewidths. Precise integrals require that the cutoff limit be equal for every peak.

Further, because of the variation of long range  $^{13}\text{C}$ –H couplings and multiplicities, the extent of incorporation of satellite contributions within the linewidth cutoff ranges will vary from group to group. Solvents often contain trace amounts of impurities, especially water, and can cause overlap problems, as can their isotopic satellites.

## Magnetic Resonance Imaging, Field Gradients, and Diffusion

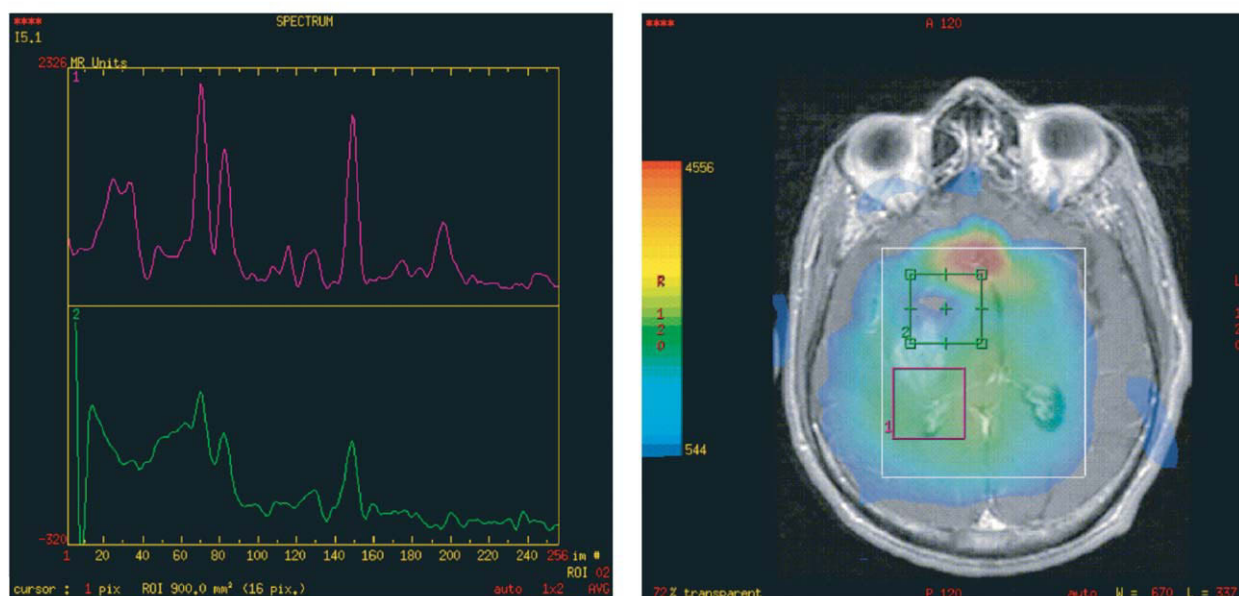

Application of magnetic field gradients adds spatial dimensions to the standard NMR experiment. The spatial location of spins – often the protons of water – is determined by making  $B_0$  spatially dependent across the sample with additional defined field gradients. The local field, which varies from point to point, determines the resonance frequency. This is the basis of MRI. Field gradients may be applied in three dimensions and generate sliced 3D images of objects such as the brain (Figure 14) and physical processes such as tablet dissolution (Figure 15). Data processing allows slicing through any desired plane. In early experiments static field gradients were used. In the simplest experiment the object was orientated at specific angles with respect to the field and the image intensity was projected onto the gradient axis. The image was reconstructed by a back projection computation. More recently pulsed field gradients are used and the image encoded in a frequency- and phase-modulated 2D array with intensity providing the third dimension. It is now possible to obtain useable images in a few seconds with such methods.

The resolution in an image is determined by the number of data points per dimension. The volume elements are called voxels. Their number is usually limited by the total acquisition time and the S/N ratio desired. The intrinsic limit for imaging of living systems is the water diffusion distance  $\sim 50\text{ }\mu\text{m}$ . In special situations  $5\text{ }\mu\text{m}$  resolution has been achieved. Practical images of flow, including blood flow, have been obtained. Polarized  $^3\text{He}$  provides images of breathing function in lungs.

(B) Chemical shift metabolic image (CSI) of the brain overlaid on the anatomic image. Spectra are displayed for the selected regions. Chemical shift range is from 4.3 to 0.5 ppm. (Spectra were obtained by Dr JA Hopkins, GE Medical Systems and reproduced by permission of GE Medical Systems, Milwaukee, WI.)

**Figure 15** NMR microscopy: dissolving of a tablet in 0.1 mol l<sup>-1</sup> HCl solution. (Spectra were reproduced by permission of Bruker Biospin.)

Magnetic field gradients may also be generated with RF in homogeneous static fields. Surface coils are tuned to resonate spins at specified depths within a material. As the spins are in a homogeneous field, it is possible to resolve chemical shift information as a function of distance. Metabolic studies *in vivo*, especially of phosphate materials, provide unique information. Clinical MRI studies of disease states are becoming practical. Functional MRI is used to identify sites of neurological activity in the brain.

## Glossary

### Anisotropy

Unequally distributed in space, a common situation for electrons in bonds where symmetry is rare. Anisotropy may be spatial, magnetic, or molecular in origin. Magnetic anisotropy is created by anisotropic electron motion induced by the applied magnetic field in groups such as phenyl. The anisotropic magnetic effects generate differential chemical shifts parallel and perpendicular to  $B_0$  for groups in fixed locations close to the anisotropic group.

### $B_0$ , $B_1$ , $B_2$

The magnetic fields used in the nuclear magnetic resonance experiment quantified by their strengths.  $B_0$  is the large static field generated by the instrument magnet. Its direction defines the  $z$ -axis.  $B_1$  is the RF electromagnetic field oscillating close to the resonance frequency of the observed nucleus. The strength of  $B_1$  is determined by its amplitude. Its direction is usually perpendicular to  $B_0$ .  $B_1$  is applied as an oscillating current in a tuned coil.  $B_2$  is similar to  $B_1$  but is tuned to the nucleus to be decoupled and is often of higher amplitude.

### Bloch decay

This is also known as the free-induction decay (FID). The summed nuclear response detected by the receiver as the magnetization induced by an excitation

	<p>pulse decays to steady state with time constant <math>T_2^*</math>. The response is digitized and Fourier transformed to produce the observed spectrum.</p>
Chemical shift	<p>The position of a nuclear resonance in the spectrum. The chemical shift is specified on the <math>\delta</math> scale relative to a reference resonance. The chemical shift is characteristic of the local electronic environment of the nucleus and is used to identify functional groups.</p>
Chemical shift anisotropy (CSA)	<p>Chemical shift is a tensor quantity and depends on the molecular orientation with respect to the applied magnetic field. Different electron circulations induced by the applied field generate magnetic fields that differentially shield the nucleus depending on molecular orientation. The CSA is the difference between the extreme values of the chemical shift observable in solids but averaged to zero in solution (see Figure 16).</p>
Coalescence	<p>The point at which two separate peaks merge to a single unresolved peak. Coalescence usually refers to a system undergoing chemical exchange and exhibiting exchange-line broadening.</p>
Composite pulse	<p>A sequence of RF pulses designed to generate a desired spectral response. The individual pulses within a composite pulse may vary in time, frequency, and orientation to achieve the desired response. Composite pulses are commonly used to invert spins over a broad frequency range where a single pulse gives imperfect inversion far from resonance. Composite pulses are also used for excitation of selected frequencies.</p>
Coherence	<p>Processes are said to be coherent when they maintain a fixed-time or phase relationship with respect to each other. The Larmor precession frequencies are brought to coherence by an RF pulse, for example, generating <math>x</math>-<math>y</math> magnetization. Phase coherence is used in pulsed field gradient experiments to selectively detect different quantum spin states.</p>
Continuous wave (CW)	<p>NMR spectroscopy performed with time-independent fixed-frequency excitation and/or detection. From 1950 to 1975, most spectrometers operated in CW mode with nuclei being brought to the fixed resonance frequency by sweeping the <math>B_0</math> magnetic field. Fourier</p>

**Figure 16** Spectral lineshapes for powdered solids. (A) Peak doublet produced by dipole coupling between two spin  $1/2$  nuclei. The doublet is composed of two parts (shown dotted). They correspond to the observed proton flip occurring when its neighbor is spin up (left) or spin down (right). The indicated turning points correspond to the angle between the internuclear vector and  $B_0$ . (B) Chemical shift anisotropy pattern with shielding tensor components  $\sigma_{11}$ ,  $\sigma_{22}$ , and  $\sigma_{33}$ . (C) Combined DD and CSA spectrum. Note that this is not simply (A) + (B). (Reproduced with permission from Power WP and Wasylishen RE (1991) In: Webb GA (ed.) *Annual Reports in NMR Spectroscopy*, vol. 23, p. 17. London: Academic Press.)

transform spectrometers by contrast operate at fixed field and use broadband frequency excitation and detection. Continuous wave may also refer to fixed-frequency continuous decoupling experiments.

**Correlation time ( $\tau_c$ )** The mean time for a molecule or molecular fragment to rotationally diffuse

	through one radian. May also refer to the inverse of the most probable angular frequency for rotational motion.		
Coupling constant	Nuclei are coupled when their energies depend on their mutual spin orientations. The magnitude of the interaction is the coupling constant, which is independent of magnetic field. Coupling may be through bond ( <i>J</i> coupling), or through space (dipole coupling). Dipole coupling is inversely proportional to the third power of the internuclear distance and depends on the orientation of the spin pair to the magnetic-field direction. <i>J</i> coupling is transmitted by the bonding electrons and attenuates with the number of intervening bonds. <i>J</i> coupling confirms nuclear connectivity.	Dipole–dipole coupling	The dipole–dipole coupling between two nuclei is given by: $D_{AB} = (\mu_0/4\pi)\gamma_A\gamma_B\hbar(3\cos^2\theta_{AB} - 1)/r_{AB}^3 \cdot 2\pi$ where A is the observed nucleus, B is neighboring nuclear dipole, $\theta_{AB}$ is the angle the A–B internuclear vector makes with the applied field direction, and $r_{AB}$ is the through-space internuclear distance. The two possible spin states of one nucleus differ in energy by the coupling to the magnetic field of the second spin dipole (see Figure 16).
		Extreme narrowing	The fast motion regime where molecular motion is sufficiently rapid that $\omega_0\tau_c \ll 1$ . Under these conditions, chemical shift anisotropy and dipole–dipole interactions are averaged to zero.
Cross polarization with magic angle spinning (CPMAS)	A combination of techniques to narrow signals and facilitate observation of high-resolution spectra of solids. Cross-polarization enhances the sensitivity of low abundance and low $\gamma$ -nuclei by transferring polarization from high abundance, high $\gamma$ -nuclei such as protons. See also magic angle spinning.	Exchange broadening	When two resonance frequencies interchange on a timescale that is of the order of the inverse of the frequency difference between them, exchange broadening occurs. When the exchange rate matches the frequency difference, the linewidth broadens to a maximum comparable to the frequency difference. Exchange may involve change in chemical shift and/or coupling constant, bond breaking, conformational change, etc.
Cross polarization	The exchange of magnetic polarization from one nuclear type to another, e.g., $^1\text{H}$ to $^{13}\text{C}$ . Exchange requires an energy match and a coupling interaction for polarization to be transferred. Usually employed to increase the sensitivity of low-frequency low-abundance nuclei using the polarization generated by high-frequency, high-abundance nuclei.	Free induction decay	See Bloch decay.
		Fermi contact	The major magnetic interaction between the electron and the nucleus. It is the major contribution to hyperfine coupling and is maximized for S electrons because of their high spin density at the nucleus.
Decoupling and double resonance (DD)	The use of high-power resonant RF to collapse coupling interactions to zero. Versions include homonuclear (observed and decoupled nuclei have the same $\gamma$ ), heteronuclear (observed and decoupled nuclei with different $\gamma$ ), and noise (for wide frequency coverage). With low-power selective irradiation it is possible to map coupled-energy diagrams and transfer polarization.	Field gradient	A magnetic field applied to make the resonance frequencies depend – usually linearly – on the location of the spins in the sample. Specifically oriented coils in the probe generate fields ( $\sim 100\text{ mTm}^{-1}$ ) in the <i>x</i> , <i>y</i> , and <i>z</i> directions. More complex gradients can be created by appropriate coil design (e.g., shim coils). Pulsed field gradients are used to measure diffusion and to select multiple quantum coherences. See also MRI.
Diamagnetic	Repelled from a magnetic field – opposite of paramagnetic; raised in energy in the presence of a magnetic field. Most molecules with all electrons paired are diamagnetic. Diamagnetic shielding contributions reduce the static magnetic field at the nucleus causing it to resonate at lower frequency.	Fourier transform (FT)	The mathematical operation for interconverting two related variables such as time and frequency. Fourier showed that any time-dependent function could be represented equivalently by the sum of a
Dipole	A nucleus with $I = 1/2$ acts as a magnetic dipole having a north and south pole. Each dipole is associated with a local		

	series of frequency functions such as sin and cos waves. The process of Fourier transformation converts the digitized Bloch decay into a frequency spectrum.		
Hahn spin echo	The recovery of signal following a $90^\circ$ – $t$ – $180^\circ$ – $t$ – pulse sequence. For example, a FID decays rapidly in an inhomogeneous field because different parts of the sample resonate at different frequencies. When a $180^\circ$ pulse is applied, at time $t$ after the excitation pulse, the signal reappears after an additional time $t$ – the Hahn echo. Alternatively, if the FID decays because of spin exchange processes ( $T_2$ ) no echo will occur.	Lock or field/frequency lock	A method for accurately maintaining (locking) the static magnetic field at a fixed value. The frequency of a nuclear magnetic resonance signal – commonly deuterium from a deuterated solvent – is held at constant value by a field/frequency feedback loop to compensate for any magnetic field drift during an experiment.
Hartmann–Hahn match	A method for allowing energy exchange between dipolar coupled nuclei with different $\gamma$ . No exchange is possible in the static field alone as the spin quanta differ in energy at common $B_0$ fields. However, the precession frequencies can be made equal about the $B_1$ RF field. The match requires that amplitudes be adjusted so that $\gamma_A B_{1A} = \gamma_X B_{1X}$ . Population and energy transfer is now possible.	Magic angle spinning (MAS)	The process of spinning a sample, usually solid, rapidly about an axis set at $54.7^\circ$ ( $\arccos 1/\sqrt{3}$ ) with respect to the static field. The magic angle corresponds to the body diagonal of a cube. Spinning about this axis averages over the three spatial dimensions equally. MAS is used to average CSA.
Homospoil	The application of a brief field gradient pulse to the shim coils to vary $B_0$ across the sample. This destroys any residual $x$ – $y$ magnetization because the magnet homogeneity has been spoiled and frequencies dispersed proportionally.	Magnetic moment ( $\mu$ , $M$ )	Each nuclear spin has a magnetic moment, $\mu$ quantified in units of its spin angular momentum. Values of $\mu$ in units of the Bohr magneton, $\beta$ , are recorded according to different conventions. For protons, the values are 5.5854 with $\mu = \gamma\hbar$ ; 2.7927 with $\mu_z = \gamma\hbar I$ for the $z$ component of spin $I$ , or 4.8372 with $\mu = \gamma\hbar\sqrt{I(I+1)}$ where the total magnetic moment is the scaling factor. The observable component $p$ is given by $m_I = \mu/\sqrt{I(I+1)}$ where $m_I$ is the magnetic quantum number of an individual spin which has allowed values $-I, -I+1, \dots, I-1, I$ . The vector sum of the individual spin moments gives the bulk observable magnetic moment which is denoted by $M$ .
Knight shift	The large chemical shifts observed in the nuclear magnetic resonance of molecules with unpaired electrons – especially metals. It arises because the magnetic environment of the nucleus is dominated by the electron paramagnetism since $\gamma_e \gg \gamma_N$ . Shifts to high or low frequency are observed depending whether the $\alpha$ or $\beta$ electron spin state is low energy and hence more populated.	Magnetogyric ratio ( $\gamma$ )	The proportionality constant, $\gamma$ , between the resonance frequency of a particular nucleus and the magnetic field strength.
Larmor frequency	The precession frequency of the nuclear spin dipole when torqued by a magnetic field. The Larmor frequency is equal to the nuclear resonance frequency.	Magnetic resonance imaging (MRI)	The use of nuclear magnetic resonance to measure the spatial distribution of nuclei, particularly water protons. Magnetic field gradients generate spatial dependence of the resonance frequency. Three-dimensional images are constructed from the signals.
Lineshape, linewidth	A nuclear magnetic resonance line is usually found to have one of two ideal lineshapes – Gaussian, or more often, Lorentzian. A Gaussian line is found when there is a random distribution of static fields within the sample. A Lorentzian line by contrast arises because the spin lifetime follows a first-order decay law. Weighting functions can be applied to a free-induction decay to generate	Nuclear magnetic resonance (NMR) timescale	The NMR timescale most commonly refers to spin lifetimes of milliseconds to seconds and chemical exchange kinetic processes. The actual time is in the range $0.1/\Delta\omega - 10/\Delta\omega$ where $\Delta\omega$ is the frequency difference in $\text{s}^{-1}$ between exchanging signals. The NMR timescale

	may also refer to the nanosecond regime when relaxation processes are being discussed. This timescale relates to the correlation time, $\tau_c$ , for molecular motion involved in relaxation.		
Nuclear Overhauser effect (nOe)	The change in signal intensity of a nucleus when a transition of an adjacent spin is irradiated. The observed and irradiated spins must be dipole coupled to one another. The observation of an nOe implies the spins are within 0.1–1 nm of each other.	Quadrupole	A nucleus with $I \geq 1$ . The nucleus responds to both magnetic fields and electric-field gradients caused by the nonspherical distribution of charge induced by bonding.
Nyquist criteria/frequency	A set of fundamental criteria establishing the limits for digital data acquisition. For example, a minimum of two points taken in a specified time are required to define a wave and its frequency. The Nyquist frequency is the maximum frequency represented accurately in a spectrum and is set by the dwell time in the digital acquisition.	Radiofrequency (RF)	The energy difference between nuclear spin states in the magnetic field used for nuclear magnetic resonance falls in the RF region (kHz–GHz) of the electromagnetic spectrum. Thus, a source of RF electromagnetic radiation is used to excite nuclear spins.
Paramagnetic	Attracted into a magnetic field. Molecular paramagnetism is generated by unpaired electron spins. A paramagnetic interaction is one where energy is lowered by increasing the magnetic field. Electron orbital angular momentum may also generate paramagnetism. A paramagnetic chemical shift is to higher frequency.	Relaxation	The process where nuclei dissipate excess spin energy into other forms of molecular energy especially rotation and translation. $T_1$ (spin–lattice, longitudinal) and $T_2$ (spin–spin, latitudinal) relaxation are the independent time constants for the dissipation of $z$ and $x$ – $y$ magnetization, respectively. Spin–lattice relaxation – time constant $T_1$ – involves a change in the total $z$ magnetization of the sample as quanta of spin energy are exchanged with the surroundings. Spin–spin relaxation, $T_2$ , is the time constant for decay of spin order and coherence commonly represented as $x$ – $y$ magnetization. There is no energy exchange with the surroundings and spin order is randomized. Spin order is commonly randomized by mutual spin flips between dipolar coupled pairs. The $x$ – $y$ magnetization decays with time constant $T_2$ to its equilibrium value of zero. As there is no magnetic field in the $x$ – $y$ plane there is no $x$ – $y$ magnetization at equilibrium. When a $B_1$ or $B_2$ RF field is present, the $T_2$ relaxation time constant is replaced with $T_{1\rho}$ – relaxation in the rotating frame.
Polarization	The total net magnetization of spins created by unequal spin populations. When nuclear spins are placed in a magnetic field their random motion becomes orientated with respect to the field direction. For $I = 1/2$ nuclei, there are two spin states orientated with or against the field. At equilibrium the spin states are populated according to the Boltzmann distribution and so there are more spins in the lower energy state. This population imbalance creates an overall magnetization of the sample – the spins are polarized. Pulses generate nonequilibrium polarizations and polarization may be transferred between spins.	Residual dipolar coupling	In samples containing large anisotropic molecules such as phages and other additives, the motion of the small and large molecules becomes anisotropic. As a result the $(1 - 3 \cos^2 \theta)$ term in the dipole coupling expression does not average to zero. Residual dipole couplings between closely spaced nuclei may then be detected and correlated with molecular geometry.
Pulse	A short, usually microsecond, burst of RF electromagnetic radiation. The fixed RF is chosen to be close to the nuclear resonance frequency to be excited. The shorter the pulse, the broader the frequency range that may be excited. The pulse is applied through a conducting coil wound closely around the sample. Pulse nuclear magnetic resonance involves spectral excitation with a short	Resolution	Two peaks may only be resolved if their linewidth is smaller than the frequency difference between them. In nuclear magnetic resonance, resolution

	is usually governed by experimental factors such as magnetic field homogeneity and digital resolution. Digital resolution is set by the number of data points in a spectral window which in turn depends on total acquisition time. Absolute resolution is set by the spin lifetime which establishes the linewidth at half height. See also $T_2$ .		
Resonance	When the RF equals the energy gap between spin states that differ by one in spin quantum number, the spins are said to be in resonance.	Second-order coupling	This refers to the patterns observed for $J$ -coupled multiplets. In a first-order spectrum, the lines for spins coupled to groups containing $n$ equivalent atoms of spin $I$ are split into $2nI + 1$ lines. The spacing on both partners are equal, and equal to $J$ . This requires that the chemical shift difference between coupled spins is at least ten times $J$ . Second-order effects occur when $\Delta\delta \sim J$ , so called strong coupling. As $\Delta\delta$ approaches $J$ , at first line intensities become unequal within the multiplet and are canted towards the mean chemical shift (haystacking). Next, line spacings become unequal and differ from $J$ . When $\Delta\delta \sim J$ extra lines appear in the spectrum, intensities vary widely, and line spacings do not match $J$ .
Rigid lattice	The slow motion regime where $\omega_0\tau_c \gg 1$ and chemical shift anisotropy and dipole-dipole effects broaden spectra.		
Ring current	A magnetic dipole may be represented equivalently as a current loop. A magnetically anisotropic group such as a benzene ring acts as a magnetic dipole when placed in a magnetic field. The magnetic influence of such rings is often modeled as a current loop with electrons circulating around the $\pi$ system at a rate proportional to $B_0$ which is termed a ring current. Groups that are at fixed orientations relative to the magnetic dipole, ring current, have their resonances shifted by the induced ring current.	Shielding tensor	The electron motion around the nucleus induced by the applied magnetic field generates an internal magnetic field. The induced field is said to shield or screen the nucleus from the applied field and is observed as the chemical shift. The shielding tensor defines the principal values and orientation of the chemical shift in the molecular frame. The maximum difference between the principal values defines the CSA.
Rotating frame	The simplest Cartesian frame of reference to envisage for the nuclear magnetic resonance experiment is the laboratory frame with the magnetic-field direction defining the $z$ -axis. In the presence of an oscillating electromagnetic field (RF) the description of the motion of the nuclear spins and the net magnetization is complex in the laboratory frame. A mathematical transformation from the laboratory frame to a frame rotating at the RF oscillation frequency greatly simplifies the description of the magnetic field and the motion. (An analogy may be useful. The description of the motion of the moon in a solar coordinate system is greatly simplified by transforming to a coordinate system that rotates with the earth.) In the laboratory frame, the $x$ and $y$ coordinates are time independent, in the rotating frame the $B_1$ field is static in the $x'-y'$ plane which is rotating at the RF in the laboratory frame.	Shift reagent	A reagent which binds rapidly and reversibly to a molecule and induces a chemical shift. The common shift reagents are organometallic lanthanide complexes such as $\text{Eu(DPM)}_3$ that act as Lewis acids in nonpolar solvents. The reagents have a large magnetic anisotropy and induce substantial changes in chemical shift. The changes in shift depend on the binding constant, proximity, and orientation with respect to the binding site. The magnetic anisotropy effect is independent of the nucleus observed, so shift reagents are most effective in proton spectra.
		Shim	The adjustment of the magnet to achieve maximum homogeneity. In the early days of nuclear magnetic resonance, shimming involved physically moving the magnet pole faces relative to one another with pieces of wood (shims). On a modern spectrometer shimming is done by varying the current in carefully designed shim coils placed in specific orientations within the probe.
Saturation	The spins are said to be saturated when the spin populations are equalized by the absorption of RF energy. There is no residual $z$ magnetization and no signal can be excited.	Spectral window	The limited frequency range observed in a pulse nuclear magnetic resonance

	experiment. The spectral window is set by the dwell time for data point acquisition in the computer (see Nyquist). The strength and duration of the radio-frequency pulse also limit the frequency window that may be excited.		
Spin lock	The application of an on-resonance RF field to maintain the $x$ - $y$ magnetization in the direction of the $B_1$ field. The spin-lock pulse is usually applied immediately following a $90^\circ$ pulse in the $x$ - $y$ plane and perpendicular to the original $90^\circ$ pulse. It has the effect of fixing (locking) the $x$ - $y$ magnetization created by the initial pulse for a time of the order of $T_{1\rho}$ rather than $T_2$ .		$n$ times. During each acquisition time a free-induction decay is acquired in time $t_2$ . Fourier transformation with respect to $t_2$ will generate $n$ spectral sets with a standard frequency axis ( $F_2$ ) containing peaks modulated according to $t_1$ . A new time series is obtained by selecting each of the common frequency points in $F_2$ and following its magnitude as $t_1$ is incremented. A second Fourier transform with respect to $t_1$ and orthogonal to $t_2$ will generate new spectra with a new frequency dimension ( $F_1$ ). A 2D plot can be made with intensity providing the third dimension. New peaks are found if the $t_1$ and $t_2$ processes are correlated and occur at $\nu_{12}$ and $\nu_{21}$ in addition to the 1D frequencies at $\nu_{11}$ and $\nu_{22}$ . Pulse sequences have been developed to provide chemical shift information on one axis and coupling constant information on the other, i.e., 2D- $J$ spectroscopy. COSY (HETCOR, COLOC, HOMCOR, HMBC) spectra correlate chemical shifts of $J$ coupled nuclei, a very useful method for structure analysis. NOESY, ROESY, and TROESY spectra correlate chemical shifts of nuclei which are dipolar coupled. The higher dimension examples (3D, etc.) involve adding new timing sequences to separate variables of interest for a particular problem. Multidimensional spectra also provide enhanced peak separation in highly overlapped spectra of large proteins. 4D spectra may be created which show data with $^1\text{H}$ , $^{13}\text{C}$ , and $^{15}\text{N}$ frequency axes with intensity given by the NOESY spatial coupling information.
Spinning sidebands	Peaks in a spectrum that are separated from the true peaks by integer multiples of the sample spinning frequency. Spinning sidebands occur as sample spinning modulates the effective field at the nucleus when the sample rotates through different field strengths caused by magnetic inhomogeneities (solution) or spatially dependent fields (e.g., chemical shift anisotropy, dipole coupling, quadrupole coupling) in solids.		
Spin temperature	For a spin system at equilibrium with its surroundings the spin energy levels are populated according to the Boltzmann distribution: $n_i/n_0 = \exp(-\Delta E/kT) = \exp(-\hbar\gamma B_0/kT)$ (4). The energy gap is fixed for a given spectrometer and nucleus and so the spin population ratio is inversely proportional to absolute temperature with a calculable proportionality constant. The spin temperature of a sample is then defined by this spin population ratio. For example, following a $90^\circ$ pulse when the spin populations are equal, the temperature is said to be infinite. It is possible to create a negative spin temperature by inverting the spin population with a $180^\circ$ pulse.	$x$ - $y$ Magnetization ( $M_{xy}$ )	The instantaneous value of the magnetic moment of the sample along the axis perpendicular to the $B_0$ field. In the laboratory frame, the $x$ - $y$ magnetization is rotating with the Larmor frequency. It varies with time constant $T_2$ and has an equilibrium value of zero.
$T_1$ and $T_2$	The spin-lattice and spin-spin relaxation times. See Relaxation.	Zeeman energy	The energy of the nuclear spin states with different spin quantum numbers in a magnetic field. Often used to describe phenomena where the energy is proportional to the strength of the magnetic field.
2D, 3D, 4D, etc., NMR	Nuclear spins may be perturbed by an enormous variety of pulse sequences. If the response of the spin system is detected as a function of independent time variables, subsequent Fourier transformation with respect to each time set will provide an independent frequency dimension for each time sequence. For example, a set of $n$ free-induction decays could be obtained with the sequence Pulse- $t_1$ -Pulse- $t_1$ -Acquire with the time delay $t_1$ incremented	Zeugmatography	The original name given to MRI by its inventor, Paul Lauterbur.
		$z$ -Magnetization ( $M_z$ )	The instantaneous value of the magnetic moment of the sample along the axis of the applied field ( $z$ -axis). It varies with time constant $T_1$ and has an equilibrium value denoted $M_0$ .

### Introduction

After the first observation of bulk phase nuclear magnetic resonance (NMR) in 1945 and the realization that it would be useful for chemical characterization that came with the discovery of the chemical shift in 1951, it was only a few years before the first commercial spectrometers were being produced. By the end of the 1950s, a considerable number of publications on the application of NMR to chemical structuring and analysis problems had appeared and then during the 1960s and later, it became clear that useful answers could be obtained in biological systems. Since then the applications and the consequential instrument developments have diversified and now NMR spectroscopy is one of the most widely used techniques in chemical and biological analyses. The very high specificity, the exploratory nature of the technique without the need to preselect analytes,

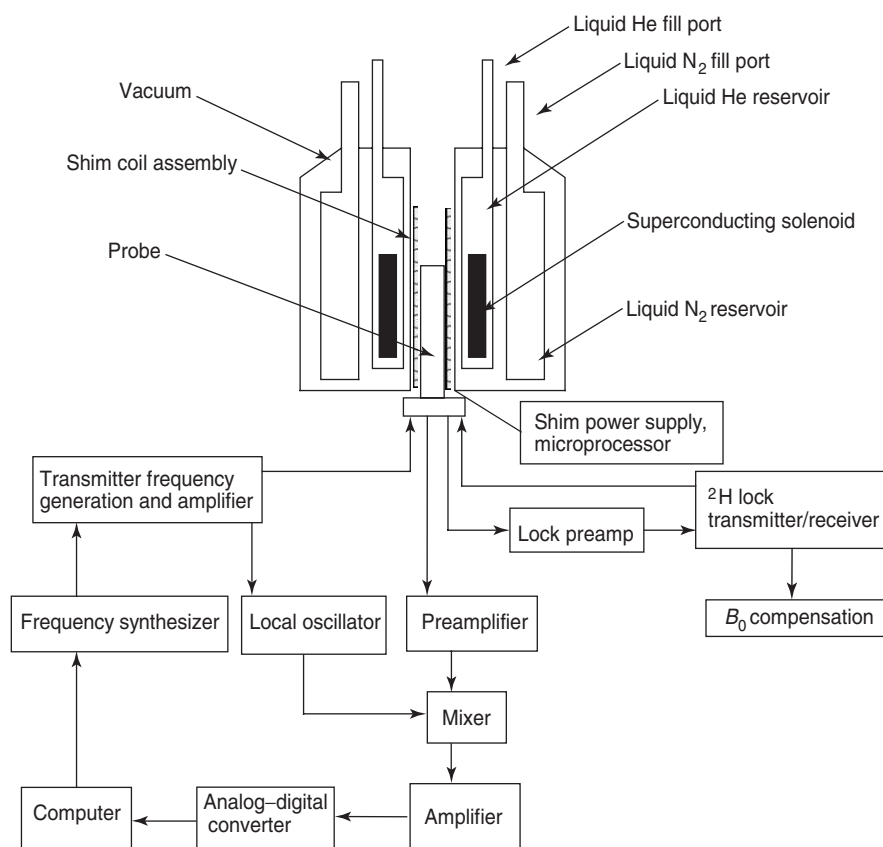

and its nondestructive nature have made it very useful despite its lower sensitivity compared to some other spectroscopic methods.

A general description is given here of the way in which a modern NMR spectrometer operates, of the various components that go into making a complete system, and the particular role that they play. Today, with the level of computer control present in modern spectrometers, this naturally includes a description of both the hardware and software. An overview diagram of the components of a high-resolution NMR spectrometer is given in Figure 1.

### Components and Principles of Operation of NMR Spectrometers

#### Continuous Wave and Fourier Transform Operation

For many years, all commercial NMR spectrometers operated in continuous wave (CW) mode. This type of operation required a sweep of the NMR frequency or the magnetic field over a fixed range to bring each nucleus into resonance one at a time. These scans for

**Figure 1** A block diagram of the principal components of a modern NMR spectrometer.

$^1\text{H}$  would take typically 500 s to avoid signal distortion. Since most NMR spectra consist of a few sharp peaks interspersed with long regions of noise, this was a very inefficient process. A fundamental paper by Ernst and Anderson in 1966 pointed out the favorable gain in efficiency that could be obtained by simultaneously detecting all signals. This is achieved by the application of a short intense pulse of radio-frequency (RF) radiation to excite the nuclei followed by the detection of the induced magnetization in an RF detector coil as the nuclei relax. The decaying, time-dependent signal, known as a free induction decay (FID) is then converted to the usual frequency domain spectrum by the process known as Fourier transformation. The efficient calculation of the digital Fourier transform (FT) requires the number of data values to be a power of two, typically perhaps 16 K points for modest spectral widths, up to 128 K or even 256 K points for wide spectral widths on high-field spectrometers (1 K is 1024 or  $2^{10}$  points). Acquisition of a  $^1\text{H}$  FID requires typically a few seconds and opens up the possibility of adding together multiple FID scans to improve the spectrum signal-to-noise ratio (S/N) since for perfectly registered spectra, the signals will co-add but the noise will only increase in proportion to the square root of the number of scans. The S/N gain therefore is proportional to the square root of the number of scans. This for the first time made routine the efficient and feasible acquisition of NMR spectra of less sensitive or less abundant nuclei such as  $^{13}\text{C}$ .

### The Magnet and Associated Components

The most fundamental component of an NMR spectrometer is the magnet. Originally, this would have been a permanent or electromagnet and these provided the usual configurations for field strengths up to 1.41 T (the unit of magnetic field strength is the tesla (T) equivalent to 10 000 gauss (G)), corresponding to a  $^1\text{H}$  observation frequency of 60 MHz. Because the sensitivity of the NMR experiment is proportional to about the  $3/2$  power of the field strength, denoted  $B_0$ , the drive to higher and higher magnetic fields has been remorseless. This led the commercial NMR manufacturers to develop stronger electromagnets for NMR spectroscopy. This took the highest field strengths to 100 MHz for  $^1\text{H}$  observation, i.e., 2.35 T. Materials suitable for electromagnets have maximum saturation field strengths at about this value. Because of the continued need for even higher field strengths, the development of magnets based on superconducting solenoids was commenced. In this case, the magnetic field is generated by a current circulating in a coil of superconducting wire

immersed in a liquid helium Dewar at 4.2 K. This bath is shielded from ambient temperature by layers of vacuum and a jacket of liquid nitrogen at 77 K, which is usually topped up at a weekly interval. A liquid helium refill is carried out at  $\sim 2$ –3-month intervals depending on the age and field strength of the magnet. The initial development of superconducting magnets was at 5.17 T corresponding to 220 MHz for  $^1\text{H}$  and operated in CW mode. Until  $\sim 1972$ , this represented the highest field strength, but then at regular intervals the available field strength gradually increased along with the emergence of wider bore magnets enabling the incorporation of larger samples. Thus, a 270 MHz spectrometer was produced along with a wide-bore 180 MHz machine and then the field was increased to allow  $^1\text{H}$  observation at 360, 400, 500, 600, 700, 750, and 800 MHz, and the present limit of any machine yet delivered to a customer is at 900 MHz (2003). For instruments that operate for  $^1\text{H}$  NMR at 700 MHz or greater, the liquid helium bath is kept at  $\sim 2$  K by a pumped refrigeration system so that the higher currents needed for the higher fields can be achieved. A modern high-field NMR spectrometer using this type of superconducting magnet is shown in Figure 2. One major achievement has been the introduction of actively shielded magnets in which the stray magnetic field from the main solenoid is reduced in extent by opposing magnetic field coils. This brings the stray field (e.g., the 5 G limit, outside of which magnetic metal objects, and people with cardiac pacemakers

**Figure 2** A modern high-resolution NMR spectrometer. The superconducting magnet is shown at the center, in this case providing a field of 21.2 T corresponding to a  $^1\text{H}$  observation frequency of 900 MHz. On the right is the console containing the RF, other electronics, and the temperature control unit (photograph reproduced by permission of Bruker Biospin GmbH, Rheinstetten, Germany).

should be kept), to  $<1.5$  m for a 600 MHz NMR system. This facilitates the adjacent positioning of other equipment and even allows NMR spectrometers to be much closer to each other than before. Nowadays, apart from very basic routine low-field spectrometers used, for example, for monitoring chemical reactions, all NMR spectrometers are based on superconducting magnets.

At present, 900 MHz for  $^1\text{H}$  NMR spectroscopy is the current commercial limit and the first machines at this field have been produced. Higher fields must be on the way and clearly an emotive figure would be the 1 GHz  $^1\text{H}$  NMR spectrometer. This development will require both the design of transmitter and detection technology working at or beyond the limit of RF methods and developments in superconducting wire technology. Although the higher field strengths provide greater spectral dispersion and yield better sensitivity, it may be that some applications involving heavier nuclei are less suited to such high fields because of the field dependence of certain mechanisms of nuclear spin relaxation that could cause an increased line broadening and hence lower peak heights and detectability.

Inserted into the magnet is the NMR detector system or probe. High-resolution NMR spectra are usually measured in the solution state in glass tubes of standard external diameters, 5 mm being the most common, but larger ones (10 mm) are used where improved sensitivity is required and sample is not limited. Also, a range of narrow tubes is available for limited sample studies (4 mm, 3 mm, and even smaller specially shaped cavities such as capillaries or spherical bulbs, etc.). Very small sample sizes can be accommodated in specialized micropubes with sample volumes in the microliter range. As described below, it is now possible to measure NMR spectra using special probes in a flow-injection mode avoiding the use of sample tubes completely. The probe contains tuneable RF coils for excitation of the nuclear spins and detection of the resultant signals as the induced magnetization decays away. A capability exists for measuring NMR spectra over a range of temperatures, typically  $-150^\circ\text{C}$  to  $+200^\circ\text{C}$ .

A major advance in detection of NMR signals has been the development of probes in which the RF coil and the preamplifier are cooled close to the temperature of liquid helium, but with the sample remaining at ambient temperature. These so-called cryoprobes have a S/N ratio improvement of  $\sim 500\%$  over conventional probes of the same sample diameter. This is because the thermal noise level in the circuitry scales approximately as the square root of the ratio of the absolute temperatures. There are some limitations to this improvement for highly conducting

solutions such as strongly ionic solutions, but these can be minimized by the use of smaller sample diameters thereby reducing dielectric losses.

Even though modern high-resolution magnets have very high field stability and homogeneity, this is not sufficient for chemical analysis, in that it is necessary to resolve lines to about a width of 0.2 Hz and, at a typical common operating frequency of 600 MHz, this represents a stability of one part in  $3 \times 10^9$ . This performance is achieved in two ways. Usually, deuterated solvents are used for NMR spectroscopy to avoid the appearance of solvent peaks in the  $^1\text{H}$  spectrum. Deuterium is an NMR active nucleus and the spectrometer will contain a  $^2\text{H}$  channel for exciting and detecting the solvent resonance. Circuitry exists in the spectrometer for maintaining this  $^2\text{H}$  signal exactly on resonance at all times by detecting any drift from resonance caused by inherent magnet drift or room temperature fluctuations and for providing an error signal to bring the magnet field back on resonance by applying small voltages through subsidiary coils in the magnet bore. This is known as a 'field-frequency lock' and it means that successive scans in a signal accumulation run are exactly coregistered. To improve the homogeneity of the magnet an assembly of coils is inserted into the magnet bore (shim coils). These consist of  $\sim 20$ –40 coils specially designed so that adjustable currents can be fed through them to provide corrections to the magnetic field in any combination of axes to remove the effects of field inhomogeneities. The criterion of the best homogeneity is based upon the fact that when the  $^2\text{H}$  lock signal is sharpest (i.e., the most homogeneous field) the signal will be at its highest. The currents in the shim coils are usually adjusted (called shimming), therefore, to give the highest lock signal. Alternatively, it is possible, although less common, to shim on the  $^1\text{H}$  NMR signal. This whole process is now largely computer-controlled in modern spectrometers. A form of shimming the magnetic field to obtain high homogeneity has arisen from concepts from magnetic resonance imaging (MRI). Here, the inhomogeneous magnetic field is mapped in three dimensions initially using the application of field gradients applied along the three orthogonal axes. Then small currents can be applied to the shim coils in a computer-optimized fashion over several iterations of the process. Often for subsequent operation only the homogeneity along the magnetic field direction needs to be optimized using a single gradient map.

NMR spectra were usually measured with the sample tube spinning at  $\sim 20$  Hz to further improve the NMR resolution. This can introduce signal sidebands at the spinning speed and its harmonics, and

on modern high-field machines with improved resolution, this is becoming less necessary and is undesirable in some cases.

In analytical laboratories where large numbers of samples have to be processed, it is accepted that automatic sample changers can play a large part in improving efficient use of the magnet time. These devices allow the measurement of up to  $\sim 120$  samples in an unattended fashion with the insertion and ejection of samples from the magnet under computer control. Automatic lock detection and optimization, sample spinning, NMR receiver gain, and shimming are also standard. The data are acquired automatically and can be plotted and stored on backing devices. As an additional aid in routine work, it is possible to purchase an automated work bench that will produce the samples dissolved in the appropriate solvent in an NMR tube starting from a solid specimen in a screw-capped bottle; it will also dispose of samples safely and wash the NMR tube.

If it is necessary to measure NMR spectra on large numbers of samples, e.g., from combinatorial chemical synthesis or from large biofluid studies, then flow-injection probes are now in general use. Samples can be made up in 96-well plates using a specialized robotic system; the plate is then transferred to a second robotic system in which the contents of a well can be extracted and flowed into the NMR probe where the sample is stopped and any NMR experiments carried out. After measurement, the sample is then sent back to the same well, to a well in a different plate, or to waste as desired.

### Excitation, Detection, and Computer Processing of NMR Signals

The RF signal generation is derived ultimately from a digital frequency synthesizer that is gated and amplified to provide a short intense pulse. Pulses have to be of short duration because of the need to tip the macroscopic nuclear magnetization by  $90^\circ$  or  $180^\circ$  and at the same time to provide uniform excitation over the whole of the spectral range appropriate for the nucleus under study. Thus, for  $^{13}\text{C}$  NMR, for example, where chemical shifts can cover  $>200$  ppm this requires a 25 KHz spectral width on a spectrometer operating at 500 MHz for  $^1\text{H}$ , which corresponds to 125 MHz for  $^{13}\text{C}$ . To cover this range uniformly requires a  $90^\circ$  pulse to be  $<10\ \mu\text{s}$ . The RF pulse is fed to the NMR probe which contains one or more coils which can be tuned and matched to the required frequency, this tuning changing from sample to sample because of the different properties of the samples such as the solution dielectric constant. The receiver is blanked off during the pulse and for a

short period afterwards to allow the pulse amplifier to ring down. The receiver is then turned on to accept the NMR signal that is induced in the coil as the nuclei precess about the field and decay through their relaxation processes. The detection coil is wound on a former as close as possible to the sample to avoid signal losses and is oriented with its axis perpendicular to the magnetic field. In a superconducting magnet the sample tube is aligned along the field, and a simple solenoid coil around the sample that would provide the best S/N is not possible. Consequently, most detector coils are of the saddle type. However, in a new generation of microsample coils using the flow-injection principle it is possible to have the sample chamber horizontal and hence a solenoid coil perpendicular to the magnetic field can then be used. The weak NMR signal is amplified using a preamplifier situated as close to the probe as possible, and then also in the main receiver unit where it is mixed with a reference frequency and demodulated in several stages leaving the free induction decay (FID) as an oscillating voltage in the kilohertz range. This signal is then fed to an analog-to-digital converter (ADC) and at this point the analog voltage from the probe is converted into a digital signal for data processing. ADCs are described in terms of their resolution, usually in terms of the number of bits of resolution, i.e., a typical high-field NMR FID is digitized to a resolution of 16 bits or one part in  $2^{16}$  or 65 536. If only one ADC is used to collect the NMR FID, it is not possible to distinguish frequencies that are positive from negative with respect to the pulse frequency. For this reason, the carrier frequency was set to one edge of the spectral region of interest to make sure that none of the NMR peaks were 'aliased', i.e., folded into the spectral region from outside it. This had the disadvantage of allowing all of the noise on the unwanted side of the carrier being aliased onto the noise in the desired spectral region; hence, reducing the final S/N by  $\sqrt{2}$ . To overcome this problem it is general now to collect two FIDs separated in phase by  $90^\circ$  using either two ADCs or to multiplex one ADC to two channels. This approach allows the distinction of positive and negative frequencies and means that the carrier can be set in the middle of the spectrum, the hardware filters correspondingly reduced in width by a factor of 2 and an increase in S/N by  $\sqrt{2}$ . This process is termed quadrature detection. The digital signals can then be manipulated to improve the S/N ratio or the resolution by multiplying the FID by an appropriate weighting function before the calculation of the digital FT.

Modern NMR spectrometers usually have two separate computer systems. One is dedicated to the

acquisition of the NMR FID and operates in background so that all necessary accurate timing requirements can be met. The FID is transferred, either at the end of the acquisition or periodically throughout it to enable inspection of the data, to the host computer for manipulation by the operator. These computers are based on modern operating systems such as UNIX or Windows. The computer software can be very complex and can, like any modern package, take advantage of networks, printers, and plotters. Typical operations include manipulations of the signal-averaged FID by baseline correction to remove DC offset, multiplication by continuous functions to enhance S/N or resolution, Fourier transformation, phase correction, baseline correction of the frequency spectrum, calculation and output of peak lists, calculation and output of peak areas (integrals), and plotting or printing of spectra. NMR data processing software can also be purchased from a number of companies other than the instrument manufacturers, and these often have links to document production software or provide output of NMR parameters for input into other packages such as those for molecular modeling. A number of approaches alternative to the use of FID weighting functions for improving the quality of the NMR data have been developed and are available from software suppliers. These include such methods as maximum entropy and it is possible to purchase these as supplementary items from some NMR manufacturers.

### Multiple Pulse Experiments and Multidimensional NMR

So far everything described applies to the basic one-dimensional (1D) NMR experiment when the nuclear spin system is subjected typically to a  $90^\circ$  pulse and the FID is collected. A wide variety of experiments exist in the literature and are routinely applied to measure NMR properties such as relaxation times  $T_1$ ,  $T_2$ , and  $T_{1\rho}$ , which can be related in some cases to molecular dynamics. These experiments involve the use of several pulses separated by timed variable delays and are controlled by pulse programs written in a high-level language for ease of understanding and modification. The computer system will have software to interpret the data and calculate the relaxation times using least-squares fitting routines.

Such pulse programs are also used to enable other special 1D experiments such as saturation or non-excitation of a large solvent resonance (these are different in that the former method will also saturate NH or OH protons in the molecules under study through the mechanism of chemical exchange), or the measurement of nuclear Overhauser enhancement effects

that are often used to provide distinction between isomeric structures or to provide estimates of internuclear distances. Pulse programs are also used for measuring NMR spectra of nuclei other than  $^1\text{H}$  and sometimes in order to probe connectivity between protons and the heteronucleus. In this case, pulses or irradiation can be applied on both the heteronucleus and  $^1\text{H}$  channels in the same experiment. The commonest use is in  $^{13}\text{C}$  NMR where all spin-couplings between the  $^{13}\text{C}$  nuclei and  $^1\text{H}$  nuclei are removed by 'decoupling'. This involves irradiation of all of the  $^1\text{H}$  frequencies whilst observing the  $^{13}\text{C}$  spectrum. In order to cover all of the  $^1\text{H}$  frequencies, the irradiation is provided as band of frequencies covering the  $^1\text{H}$  spectral width; this is consequently termed noise decoupling or broadband decoupling. Alternatively, it is possible to obtain the effect of broadband decoupling more efficiently by applying a train of pulses to the  $^1\text{H}$  system, this being known as composite pulse decoupling.

A whole family of experiments have been developed that detect low-sensitivity nuclei such as  $^{13}\text{C}$  or  $^{15}\text{N}$  indirectly by their spin coupling connectivity to protons in the molecule. This involves a series of pulses on both  $^1\text{H}$  and the heteronucleus but allows detection at the much superior sensitivity of  $^1\text{H}$  NMR. Special probes have been developed for such 'indirect detection' experiments in which the  $^1\text{H}$  coil is placed close to the sample, and the heteronucleus coil is placed outside it, the opposite or 'inverse geometry' to a standard heteronuclear detection probe.

The 1D NMR experiment is derived from measuring the FID as a function of time. If the pulse program also contains a second time period that is incremented, then a second frequency axis can be derived from a second FT. This is the basis for '2D' NMR and its extension to three or even four dimensions. For example, a simple sequence such as

$$90^\circ(^1\text{H}) - t_1 - 90^\circ(^1\text{H}) - \text{collect FID for time } t_2$$

where  $t_1$  is an incremented delay, results after double Fourier transformation, with respect to  $t_1$  and  $t_2$ , in a spectrum with two axes each corresponding to the  $^1\text{H}$  chemical shifts. This is usually viewed as a contour plot with the normal 1D spectrum appearing along the diagonal and any two protons that are spin coupled to each other giving rise to an off-diagonal contour peak at their chemical shift coordinates. This simple experiment is one of a large family of such correlation experiments involving either protons alone or heteronuclei. The extension to higher dimensions has already been exploited to decrease the amount of overlap by allowing spectral editing and the spreading of the peaks into more

than one dimension. Hardware and software in modern NMR spectrometers allows this wide variety of experiments.

The increasingly complex pulse sequences used today rely on the ability of the equipment to produce exactly  $90^\circ$  or  $180^\circ$  or any other angle pulses. One way to do this is to provide trains of pulses that have the desired net effect of, for example, a  $180^\circ$  tip, but which are compensated for any mis-setting. An example of such a 'composite pulse' is  $90^\circ_x-180^\circ_y-90^\circ_x$ , which provides a better inversion pulse than a single  $180^\circ$  pulse. Many complex schemes have been invented both for observation and decoupling (especially for low-power approaches which avoid heating the sample). A universal approach to removing artifacts caused by electronic imperfections and which is also used to simplify spectra by editing out undesired components of magnetization is the use of 'phase cycling'. This allows the operator to choose the phase of any RF pulse and of the receiver and cycling these in a regular fashion gives control over the exact appearance of the final spectrum.

For spectral editing purposes or to prove some NMR spin connectivity, it can be very convenient to excite only part of a spectrum, possibly only that corresponding to a given chemical shift or even one transition in a multiplet. This approach termed 'selective excitation' is achieved by using lower-power pulses applied for a longer period of time (e.g., a 10 ms  $90^\circ$  pulse will only cover 25 Hz). Such selective pulses are often not rectangular as for hard pulses but can be synthesized in a variety of shapes such as sine or Gaussian because of their desirable excitation frequency profiles. Modern research spectrometers can include such selective, shaped pulses in pulse programs.

Another method for achieving selective detection of certain types of spin systems is through the application of pulsed magnetic field gradients. This can be used to select particular coherence pathways for spins in a multiple pulse experiment, for example, in multi-dimensional NMR spectroscopy, to crush unwanted magnetization such as solvent resonance, to measure molecular diffusion coefficients, and, hence, to edit spectra on the basis of the diffusion coefficients of the molecules giving rise to individual peaks.

## Use of NMR Instrumentation

The vast majority of NMR spectrometers are used by chemists for molecular identification purposes in solution, mainly for small organic molecules. However, NMR spectroscopy can be used in a wide variety of application areas including macromolecule structure studies (e.g., proteins, RNA, DNA, polysaccharides),

molecular interaction studies (such as drug-protein binding), and, of course, in inorganic chemistry where a wide range of nuclides have been investigated. However, for some applications specialized instrumentation and methods are necessary and these areas are summarized here.

### NMR of Macromolecules

The determination of the 3D structure of proteins in the solution state is carried out by molecular modeling based on distance and angle constraints derived from NMR spectroscopy. Through the use of extensive  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^2\text{H}$  labeling procedures, a considerable number of structures have been obtained. However, even with the use of such techniques the NMR linewidths increase as the protein molecular weight increases and it has not been possible to study large proteins. The main cause of the linewidth increases is fast  $T_2$  relaxation caused by dipolar coupling and chemical shift anisotropy combined with slow molecular motion. However, a technique called transverse-relaxation optimized spectroscopy (TROSY) overcomes this limitation by making use of cancellation of the transverse relaxation effects between the dipolar coupling and chemical shift anisotropy. This is manifested, for example, in a 2D  $^1\text{H}$ - $^{15}\text{N}$  NMR spectrum that gives four lines for each  $^1\text{H}$ - $^{15}\text{N}$  correlation and TROSY selectively observes only the one component that has the cancelled effect and hence a narrower line. This improvement in resolution allows much larger proteins to be studied. Theory predicts that the effect is dependent on the magnetic field  $B_0$ , and should be complete at 900–1000 MHz, but that advantage already exists at 750 MHz. The TROSY technique has enabled structural studies on proteins of molecular weight  $>100\,000$  Da.

### NMR of Solids

Although  $^1\text{H}$  high-resolution NMR spectroscopy is possible in the solid, most applications to organic molecules have focused on heteronuclei such as  $^{13}\text{C}$ , although there are many published studies of inorganic systems that use NMR spectra of other nuclei such as  $^{29}\text{Si}$  and  $^{27}\text{Al}$ . High-resolution studies rely on very short RF pulses, so high-power amplifiers are necessary. Similarly, because of the need to decouple  $^1\text{H}$  from an observed nucleus such as  $^{13}\text{C}$  and thereby to remove dipolar interactions not seen in liquid state, high-power decoupling is required. However, the major difference between solution and solid-state high-resolution NMR studies lies in the use of 'magic-angle-spinning' in the latter case. This involves spinning the solid sample packed into a special rotor at an angle of  $54.7^\circ$  to the magnetic

field. This removes broadening due to any chemical shift anisotropies that are manifested in the solid-state spectrum and any residual dipolar coupling not removed by high-power decoupling. Typical spinning speeds are 2–6 kHz or 120 000–720 000 rpm, although higher speeds up to 25 kHz, where the rotor rim is moving at supersonic velocity, are possible and necessary in some cases.

### Separations Directly Coupled to NMR Spectroscopy

This has become a major use of modern NMR spectrometers, since the technology became commercially available. Many types of separation have been coupled directly to NMR spectrometers, and also to mass spectrometers in parallel, for simultaneous NMR and mass spectrometry analysis and identification of eluting materials. Published approaches where separations have been directly coupled to NMR spectrometers include solid-phase extraction, liquid chromatography (LC), capillary LC, supercritical fluid chromatography, capillary electrophoresis, and capillary electrochromatography. There is now a large literature on this subject. Application areas include impurity profiles and their identity for fine chemicals, identification of drug metabolites, and characterization of natural products including those of potential medicinal use.

### NMR Imaging

A whole new specialized subdivision of NMR has arisen in the allied disciplines of NMR imaging (MRI) and NMR spectroscopy from localized regions of a larger object. Applications range from the analysis of water and oil in rock obtained from oil exploration drilling to medical and clinical studies. Thus, spectroscopic applications include the possibility of measuring the  $^1\text{H}$  or  $^{31}\text{P}$  NMR spectrum from a particular volume element in the brain of a living human being and relating the levels of metabolites seen in a diseased condition. Some experiments on smaller samples can be carried out in the usual vertical bore superconducting magnets but studies are more often performed in specially designed horizontal bore magnets with a large clear bore capable of taking samples up to the size of adult human beings. Because of the large bore, they operate at lower field strengths compared to analytical chemical applications, and typical configurations would be 2.35 T with a 40 cm bore or 7.0 T with a 21 cm bore. Clinical imagers utilize magnetic fields up to 3 T with a 1 m bore. Imaging relies upon the application of magnetic field gradients to extra coils located inside the magnet bore in all three orthogonal

axes including that of  $B_0$  and excitation using selective RF pulses. Virtually all clinical applications of MRI use detection of the  $^1\text{H}$  NMR signal of water in the subject with the image contrast coming from variation of the amount of water, or its NMR relaxation or diffusion properties in the different organs or compartments being imaged. Very fast imaging techniques have been developed that allow movies to be constructed of the beating heart or studies of changes in brain activity as a result of light or aural stimulation to be conducted.

### Industrial Analysis

Specialist tabletop machines can be purchased and these are used for routine analysis in the food and chemical industries. They operate automatically at typically 20 MHz for  $^1\text{H}$  NMR using internally programmed pulse sequences and are designed to give automatic printouts of analytical results such as the proportion of fat to water in margarine or the oil content of seeds.

There have been a number of NMR-based devices that are used to measure properties of materials that are located remotely from the NMR magnet. Examples include the use of specialized devices for oil-well logging where measurements of NMR parameters can be made down an oil well, giving information on the presence of oil and water. Similarly, a device named the NMR mobile universal surface explorer (NMR MOUSE) has been developed for applications in materials science. This can measure relaxation and diffusion properties of elastomers, industrial coatings, and objects such as rubber vehicle tyres for quality control purposes.

## Introduction

Nuclear magnetic resonance (NMR) spectroscopy, arguably the most powerful technique in chemistry, is a relatively insensitive method, but in the short time interval between the appearance of the first and second editions of the *Encyclopedia of Analytical Sciences*, considerable improvements have been made. Consequently, the range of applications that now become possible is greatly expanded as is illustrated here for the two isotopes of hydrogen, tritium ( $^3\text{H}$ ) and deuterium ( $^2\text{H}$ ); further developments are also anticipated.

## Tritium NMR Spectroscopy

Tritium ( $^3\text{H}$  or T) possesses ideal NMR properties – spin of  $\frac{1}{2}$ , high sensitivity (21% better than for  $^1\text{H}$ ,  $\gamma_{^3\text{H}}/\gamma_{^1\text{H}} = 1.06664$ , where  $\gamma_{^3\text{H}}/\gamma_{^1\text{H}}$  is the gyromagnetic ratio) and extremely low natural abundance, but because it is radioactive (a weak  $\beta^-$ -emitter with a half-life of 12.3 years, Table 1) there is the need for associated radiochemical facilities and trained

personnel and this is the main reason why, outside the companies that supply tritiated compounds, and the pharmaceutical companies that use the products, together with a small number of universities/research institutions, the technique is not widely used.

Two recent developments are likely to improve the attractions of this particular isotope. First, a whole range of microwave-enhanced procedures have been developed which allow tritiations to be carried out more rapidly, sometimes more selectively, and, finally, with the production of less radioactive waste. The latter can frequently be converted to tritiated water that can then be reused. This represents a good example of ‘Green Chemistry’.

The second development relates to NMR sensitivity. Improvements in spectrometer technology over the last 20 years of the twentieth century led to an approximate threefold increase in NMR sensitivity. Now with the development of cryoprobes there is the possibility of being able to reduce the measurement time by an order of magnitude, or more. This kind of benefit will be maximized for nuclei such as tritium that have an extremely low natural abundance.

Cooling the RF coils of a probe to cryogenic temperature improves the RF efficiency and reduces the noise generated by the coils. Further improvements can be achieved if the preamplifier is also cooled to cryogenic temperatures, as in this way the noise generated in the circuit is reduced. These objectives, despite the formidable challenges presented by the need to keep the sample temperature stable at close

**Table 1** Some of the important properties of the hydrogen isotopes

Nucleus	Natural abundance (%)	Nuclear spin	NMR sensitivity	Radioactivity
$^1\text{H}$	99.985	1/2	1	No
$^2\text{H}$	0.015	1	$9.65 \times 10^{-3}$	No
$^3\text{H}$	$< 10^{-16}$	1/2	1.21	Weak $\beta^-$ , $t_{1/2} = 12.3$ years, $E_{\text{max}} = 18$ keV, specific activity = $29 \text{ Ci mmol}^{-1}$

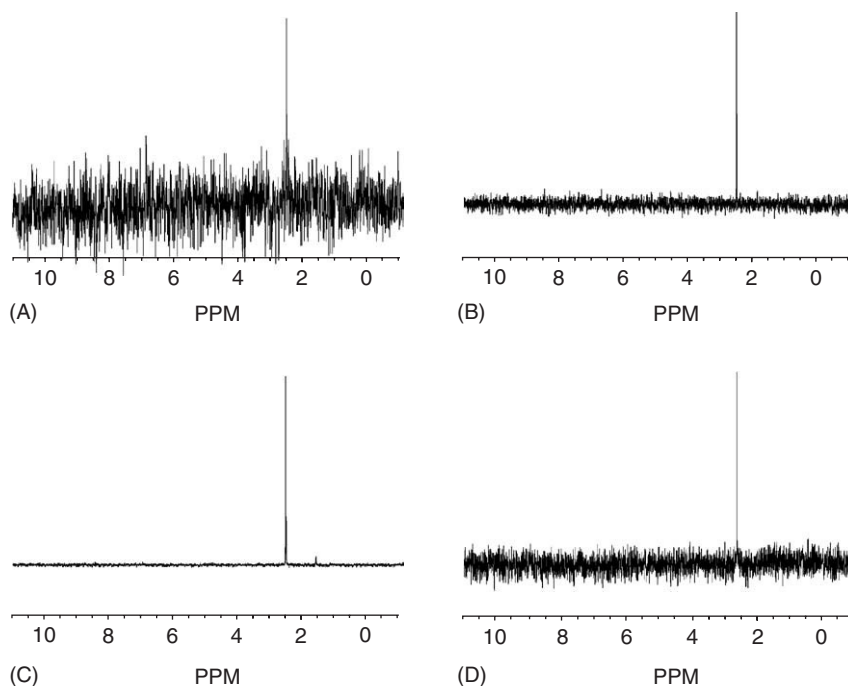

to room temperature, while the RF coils nearby are cooled to below 35 K, have now been achieved. The first tritium results have recently been published (Figure 1) and the observed improvement in signal-to-noise ratio is 4.3, equating to close on a 20-fold saving in time when acquiring a  $^3\text{H}$  NMR spectrum. In the early days of  $^3\text{H}$  NMR spectroscopy it was customary practice to use samples containing 20 mCi (740 MBq; MBq (megabecquerel) is the unit of radioactivity) of radioactivity. Nowadays, with a 500 MHz NMR spectrometer and a cryoprobe 20  $\mu\text{Ci}$  (0.74 MBq) samples are sufficient. Such an improvement is comparable to the performance expected from a 900 MHz NMR spectrometer but at a considerably lower cost. This 1000-fold improvement, if repeated in the next 35 years, would take the detection limit down to that of liquid scintillation counting. Added to the possibility of tritium magnetic resonance imaging it is clear that these techniques will continue to grow in importance.

### Applications

The major use of  $^3\text{H}$  NMR spectroscopy continues to be in the analysis of a tritiated compound produced through one of the customary routes,

e.g., hydrogenation with  $\text{T}_2$  gas of an unsaturated precursor in the presence of a homogeneous or heterogeneous catalyst, aromatic dehalogenation, again in the presence of a catalyst, borotritide-type reduction or methylation using  $\text{CT}_3\text{I}$ , and the subsequent specific activity determination. At low specific activity ( $<1 \text{ Ci mmol}^{-1}$ ),  $^3\text{H}$ - $^3\text{H}$  couplings will be absent and the  $^3\text{H}$  NMR ( $^1\text{H}$  decoupled) spectra will consist of a series of single lines, integration of which gives the relative incorporation of  $^3\text{H}$  at each site. Nuclear Overhauser effects (NOEs) are small and differential effects even smaller.  $^3\text{H}$  chemical shifts can be related to the  $^1\text{H}$  chemical shift via the Lamor frequency ratio. At high specific activity,  $^3\text{H}$ - $^3\text{H}$  coupling constants are related to the corresponding  $^1\text{H}$ - $^1\text{H}$  coupling constants, with small isotope effects, and can be used to determine the nature and proportion of different isotopomers.

There is a growing realization of the power of the technique in the catalysis area, especially when combined with the use of modern multipulse procedures such as distortionless enhancement by polarization transfer (DEPT), 2D tritium/proton correlation, 2D  $J$ -resolved NOE difference spectroscopy (NOESY), and 2D exchange spectrum (EXSY). Thus, in the

**Figure 1**  $^3\text{H}$  NMR spectra of tritiated *o*-methoxyacetophenone ( $o\text{-MeO-C}_6\text{H}_4\text{COCH}_2\text{T}$ , 68  $\mu\text{Ci}$ ) observed (A) at 320.13 MHz with a 5 mm dual-proton/tritium probe, (B) at 533.5 MHz with a 5 mm leak-proof selective excitation proton/tritium probe, (C) at 533.5 MHz with the 5 mm selective excitation proton/tritium cryoprobe, and (D) the same compound at lower activity (11  $\mu\text{Ci}$ ) using the 5 mm selective excitation proton/tritium cryoprobe at 533.5 MHz. (Reproduced with permission from Bloxsidge JP, Garman RN, Gillies DG, Jones JR, and Lu SY (2004) Development and application of a tritium cryo-probe:  $^3\text{H}$  NMR studies at the microcurie (megabecquerel) level of radioactivity. In: Dean DC, Filer CN, and McCarthy KE (eds.) *Synthesis and Application of Isotopically Labelled Compounds*, vol. 8. Chichester: John Wiley; © Wiley.)

catalytic hydrogenation of  $\beta$ -methylstyrene (1) using 5% Pd/C catalyst and  $T_2$  gas the product formed is as expected (2) but there is also clear evidence for the existence of in excess of 30 other isotopomers.

This is made possible through a combination of primary and secondary tritium isotope effects on the two methylene and one methyl groups. What is now required is a combination of developments that allows one to measure the concentration of the isotopomers as the reaction proceeds.

Although the number of research papers reporting the use of  $^3\text{H}$  NMR spectroscopy, especially by comparison to  $^2\text{H}$  and  $^{13}\text{C}$ , is small the range of applications is extensive (and is described in more detail in the book by Evans *et al.*). For example, the measurement of specific activity, optical purity, stereochemistry, solution conformation, 'kinetic' acidities, hydrogen isotope exchange, hydrogen bonding, fractionation factors, and radiolysis.

In addition, there are several reported instances of  $^3\text{H}$  NMR being used to study: reaction mechanisms, chiral methyl applications, biosynthesis, and protein-ligand interactions.

These latter studies stand to benefit most from the emergence of ultrahigh sensitive NMR spectrometers.

## Deuterium NMR Spectroscopy

Initially,  $^2\text{H}$  NMR spectroscopy studies were difficult to perform as the nuclide is inherently less sensitive ( $\sim 100$ -fold) than  $^1\text{H}$  (Table 1). Furthermore, with a nuclear spin of unity the signals were broader and resolution problems were common. In addition, the 'dynamic range' ( $100\% \rightarrow$  natural abundance) is much smaller than is the case for  $^3\text{H}$ . However, by now, the tremendous improvements that have been achieved in spectrometer performance are such that  $^2\text{H}$  is now an attractive nucleus for NMR studies. Thus, spectra can be obtained in a short time interval at the natural abundance level so that for many applications it is not necessary to spend time synthesizing deuteriated compounds. Second, the small differences that exist in the natural abundance levels of different compounds, and of even different hydrogens within the same compound, can be exploited. Finally, the development of magic angle spinning (MAS), which reduces dipolar and other anisotropic interactions, makes it possible to produce  $^2\text{H}$  NMR

spectra in the solid state that, in terms of resolution and sensitivity, rival those from liquids.

In general, the preparation of deuteriated compounds follows the same route as is used in the synthesis of tritiated organic compounds. Specifically labeled compounds are usually prepared by catalytic hydrogenation, aromatic dehalogenation, borodeuteride reduction, and methyl iodide methylation. In addition, there is a range of acid, base, and metal-catalyzed hydrogen-isotope-exchange reactions that provide routes to more generally labeled compounds. However, for preparing labeled macromolecules deuterium has a distinct advantage over tritium – deuteriated water ( $\text{D}_2\text{O}$ ) can be used in large excess thereby ensuring high deuterium incorporation, whereas with tritium, because of its radioactivity, tritiated water (HTO) has to be used in small quantities and at low specific activity ( $5 \text{ Ci ml}^{-1}$  corresponds to  $\sim 0.2\%$  isotope abundance). There are, of course, other biosynthetic routes where, e.g., a suitably tritiated amino acid can be used but on balance  $^2\text{H}$  NMR spectroscopy seems to have greater potential than  $^3\text{H}$  NMR spectroscopy in macromolecules (protein) studies.

## Applications

Hydrogen-deuterium exchange is a widely studied reaction that can be catalyzed by acids, bases, and metals. In the past,  $^1\text{H}$  NMR spectroscopy has been used to follow the decrease in one or more of the  $^1\text{H}$  integrals as a function of time. Now with the improvements in NMR magnet performance and sensitivity it becomes possible to use  $^2\text{H}$  NMR spectroscopy and follow the increase in the concentration of any deuteriated species as a function of time. In this way the kind of reactions that can be investigated can be widened to include, e.g., epoxidations, etc. (Table 2). A further advantage is that it is possible to detect reaction intermediates that are undetectable using other spectroscopic techniques. Ionic liquids, with attractive environmental features, are good solvents for many of the above-mentioned reactions.

Being able to measure  $^2\text{H}$  NMR spectra of compounds at natural abundance is the basis of an important method – site-specific natural isotope fractionation NMR for determining the authentication (and adulteration) of wines and fruit juices. The deuterium content of all hydrogen-containing sites within a compound can be determined and whilst, for example, the  $^1\text{H}$  NMR spectrum of a compound containing a  $-\text{C}_2\text{H}_5$  group is unable to recognize the very small changes in the  $^2\text{H}$  content, these can be readily achieved from the  $^2\text{H}$  NMR spectrum. The first generation of spectrometers dedicated to this work had rather low sensitivity – a small chemical

**Table 2** Reactions followed by  $^2\text{H}$  NMR spectroscopy

Oxidation		

shift discrimination at the available field and poor stability of the decoupling channel. Now with 9.4 and 11.6 T NMR spectrometers fitted with dedicated probes and state-of-the-art software good signal-to-noise ratios are obtained in a reasonable time and minute variations in natural abundance levels can be quoted with confidence. With these benefits the principle of the technique can be extended to other nuclides such as  $^{13}\text{C}$  and  $^{17}\text{O}$  and also to other problems relating to tobacco, aroma components, and polysaturated fatty acids.

Measurement of the temperature dependence of primary deuterium isotope effects ( $\delta_{\text{XH}} - \delta_{\text{XD}}$ ) on chemical shifts can provide useful information for those compounds containing an intramolecular hydrogen bond such as that depicted in (3). Varying the donor and/or acceptor provides a route to the study of compounds containing localized hydrogen bonds as well as those that display tautomerism. Larger temperature variations are observed for the latter, this being a consequence of the change in the tautomeric equilibrium upon change of temperature.

Enantiomeric differentiation of chiral compounds by NMR spectroscopy usually relies on derivatization

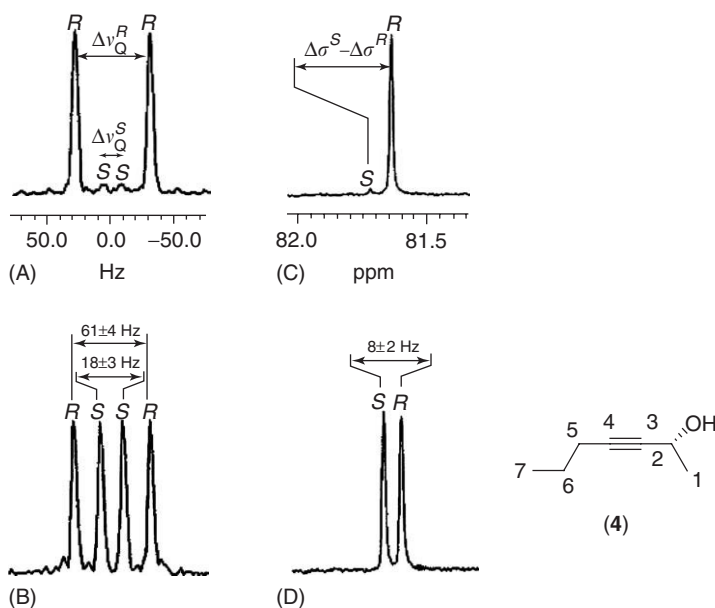

or the preparation of specific complexation agents *in situ*. Not surprisingly, therefore, the task is at its most demanding for chiral hydrocarbons. In a chiral polypeptide liquid-crystalline solvent composed of poly- $\gamma$ -benzyl-L-glutamate in chloroform it has been shown that the geometry of solutes plays an important role in the differential orientation of two enantiomers. Whilst the differential ordering effect is likely to be small in the case of *R* and *S* isomers if it could be coupled to a very sensitive order-dependent NMR interaction, such as the quadrupolar interaction for deuterium ( $I=1$ ) nuclei the basis for a differentiation exists. The large magnitude of the deuterium quadrupolar coupling constant for a  $\text{C}-^2\text{H}$  bond is  $\sim 170$  kHz, thereby ensuring sufficient difference in the residual deuterium quadrupolar splittings. This, in conjunction with the ability to obtain high-class  $^2\text{H}$  NMR spectra at natural abundance level, means that this difficult task has now been accomplished. All possible deuteriated sites within the molecule can be simultaneously probed and this without the need to synthesize any deuteriated compound. This important development can now be applied to a wide range of saturated and unsaturated chiral building blocks (Figure 2).

High-resolution NMR spectroscopy of solids only became possible with the development of MAS in which the sample is spun in a rotor at high speed (2–15 kHz), creating conditions that resemble the isotropic tumbling of small molecules in solution. At the magic angle of  $54.7^\circ$  the orientational dependence of the magnetic interactions is averaged to zero and NMR spectra can be obtained, which in terms of resolution and sensitivity rival those from liquids. The spinning speeds themselves are related to the nuclear spin coupling frequencies; consequently, by reducing the speed spinning side-bands appear in the spectra. These then provide details of dipolar couplings from which inter- and intramolecular distances can be obtained.

For nuclei such as  $^2\text{H}$  with a spin of unity the strong quadrupolar interaction ( $\sim 100$  kHz) dominates over the dipolar and chemical shift interactions and helps to simplify the analysis of the lineshapes. Selective deuterium labeling of ligands and/or proteins therefore offers considerable potential, not only for molecular distance information but also for studying the dynamics of the interactions.

## Recent/Future Developments

The importance of NMR spectroscopy has been recognized in many ways, not least by the award of various Nobel prizes over the years to Rabi, Bloch, Purcell, Ernst, Wüthrich, Lauterbur, and Mansfield. What will the future hold for deuterium and tritium

**Figure 2** (A) Natural abundance  $^2\text{H}\{-^1\text{H}\}$  signals (proton-decoupled deuterium spectrum) associated with deuterons of the methyl group 1 and (C)  $^{13}\text{C}\{-^1\text{H}\}$  signals (proton-decoupled carbon-13 spectrum) of C-4 recorded for  $R$ -(+)-**4**; (B) and (D) are obtained using the same experimental conditions as in (A) and (C), but using (±)-**4**. NMR spectroscopy? As far as the latter is concerned we are well away from being able to make measurements at natural abundance. Consequently, there is much room for improvement. Some 12 years have elapsed since the first ultrahigh field NMR magnets became commercially available and prior to this a whole new magnet technology had to be developed. The stringent demands on field strength, homogeneity, and stability require the construction of long lengths (typically 100 km) of high-quality superconducting wires. The next generation system with field strength of 23.5 T, corresponding to 1000 MHz or 1 GHz spectrometer, will require that the present  $\text{Nb}_3\text{Sn}$  alloys be replaced by the emerging high-temperature superconductors, e.g.,  $\text{BiCoSrCrO}$ , which themselves will have to have the right physical properties for the construction of the high-resolution NMR magnets.

In the short time interval (5 years) since cryoprobes were commercialized they have become an indispensable accessory for NMR. Initially, they were available on 500 MHz instruments but now they have been installed on 700 and 800 MHz spectrometers. The more recent cryostats, thanks to ingenious design, are now less sensitive to disturbances such as changes in room temperature and helium evaporation rates. All of these factors will ensure considerable improvements in the performance of these ultrastabilized magnet systems.

There is at least one other area that may be of benefit to the tritium NMR spectroscopist. In recent years there has been a trend toward miniaturization

in chemical synthesis and screening and this places an increased requirement on analytical sensitivity. Such developments have relevance to tritium chemistry as work in this area is usually undertaken at the milligram to microgram levels. Coupling techniques such as liquid chromatography–nuclear magnetic resonance (LC–NMR) have become very useful in analytical chemistry but there is one problem that relates to the maximum amount of sample (typically a few milligrams) that can be efficiently submitted for chromatographic separation. This has now been solved through the introduction of solid-phase extraction at the interface between the chromatography instrument and the NMR spectrometer. Now the entire chromatographic peak can be concentrated in the NMR detection volume. Furthermore miniaturization of the chromatographic equipment (use of micro and capillary LC separation) in conjunction with miniaturization of the radiofrequency coils and reduction of the NMR detection volume leads to considerable improvements in sensitivity. NMR spectra are usually acquired under static or stopped-flow conditions but with the necessary software multiple eluted peaks in a chromatogram can be analyzed with just one sample injection. Such applications, when transferred to the tritium area, will greatly increase its attractions as a tracer. However, there will always be the need to synthesize tritiated compounds as it is unrealistic to expect the above-mentioned improvements to lead to a situation in which  $^3\text{H}$  NMR spectra can be obtained at natural abundance level.

As far as  $^2\text{H}$  NMR spectroscopy is concerned, the application of a number of new solid-state methods is in its infancy. Molecular biology is providing opportunities for producing new proteins; ingenious biosynthetic methods can be devised for producing deuterium labeled versions and one or more of the NMR methods can be used to increase our knowledge of protein structure and dynamics and the way in which they are linked to function – one of the central problems of the life sciences. Recent work on membrane proteins, which perform essential roles in the cells of all living organisms, be it as surface receptors or transporters that mediate the uptake of nutrients or the expulsion of waste products/toxins, highlight the potential.

All of the above advances have come about without researchers addressing the important issue of what can be done to isolate and identify ultraweak signals embedded in complex ‘background noise’. Now this may be about to change, as following pioneering work in quantum physics, active signal processing technology has been developed that can increase the sensitivity of standard detection systems by up to 10 000 times. The versatility of the technology is likely to create opportunities to develop products in a number of areas, of which NMR spectroscopy is likely to be one.

## Carbon-13

**S Simova**, Bulgarian Academy of Sciences, Sofia, Bulgaria

## Introduction

Carbon-13 nuclear magnetic resonance ( $^{13}\text{C}$  NMR) undoubtedly represents one of the most significant

developments in organic structural analysis. Although its potential as an analytical tool was recognized soon after the first experiments had been carried out by Lauterbur in 1957, on molecules containing the isotope in natural abundance, it took more than a decade until the technique could be applied routinely. Today,  $^{13}\text{C}$  NMR spectroscopy has a very wide application profile and is mandatory for studying many structure, conformational, dynamic, and mechanistic problems.

Early  $^{13}\text{C}$  spectroscopists were mostly struggling with problems associated in some way with spectrometer sensitivity. NMR is an insensitive technique when compared with optical or mass spectroscopy due to the small energy difference between the ground and excited states and the long lifetimes of the excited states (typically in the order of  $10^{-3}$ – $10^3$  s). Additionally, for the carbon atoms the low natural abundance (1.108%) and the approximately four times smaller gyromagnetic ratio ( $6.728286 \times 10^7 \text{ rad s}^{-1} \text{ T}^{-1}$ ) lead to an overall sensitivity of only 1/5681 of that of the protons. The intrinsic sensitivity problems have been overcome only after the introduction of Fourier transformation (FT) methods, proton noise decoupling (Pnd), and signal averaging techniques. Additional signal enhancement could be achieved by the use of nuclear Overhauser enhancement (NOE) or polarization transfer (PT) in liquids and cross-polarization (CP) transfer in solids. Further considerable sensitivity gain is obtained by increasing the magnetic field strength. By the end of 2003, 21 T NMR spectrometers are accessible, corresponding to 226 MHz Larmor frequency for the carbon atom. Many other nuclei are more sensitive than  $^{13}\text{C}$ , e.g.,  $^{14}\text{N}$ ,  $^{23}\text{Na}$ ,  $^{31}\text{P}$ ,  $^{19}\text{F}$ , and  $^{29}\text{Si}$ ; nevertheless,  $^{13}\text{C}$  NMR is second in importance to  $^1\text{H}$  NMR and is often the only approach suitable for complex organic molecules, especially for polymers and solids. The special features that make  $^{13}\text{C}$  NMR an attractive alternative to  $^1\text{H}$  NMR or a valuable extension for the solution of structural and other analytical problems include:

- The chemical shift scale spans usually 250 ppm ( $\sim 20$  times that for protons), which allows small differences in electronic and/or steric environments around the carbon nuclei to be distinguished.
- The  $^{13}\text{C}$  NMR spectrum gives information about the carbon skeleton of the molecule, including functional groups that do not contain protons, e.g., carbonyl, cyano, etc., groups.
- The  $^{13}\text{C}$  chemical shifts are less sensitive to medium and anisotropy effects.
- $^{13}\text{C}$  peak assignment is simpler than for  $^1\text{H}$  NMR due to the lack of couplings to nearby carbons in

the broadband-decoupled spectra. Heteronuclear coupling constants could be easily distinguished.

- Determination of the number of directly bound hydrogen atoms, called multiplicity assignment, is easy through application of editing pulse sequences, e.g., distortionless enhancement by polarization transfer (DEPT) or attached proton test (APT).
- Information about molecular shape and motion can be derived from experimental spin–lattice relaxation times and measured NOE factors.
- Detailed structure elucidation is greatly facilitated through the application of various multidimensional correlation techniques for establishing through bond and through space connectivities between carbon, hydrogen, and other nuclei.
- $^{13}\text{C}$  labeling allows determination of reaction pathways in biosynthesis as well as of carbon coupling constants.
- Many analytical applications are known for solid as well as for liquid samples.

The term  $^{13}\text{C}$  NMR needs some clarification. Until  $\sim 1980$  it simply meant that the NMR spectrometer was equipped to detect  $^{13}\text{C}$  resonance lines and to ascertain  $^{13}\text{C}$  NMR parameters. An indirect approach for the latter task was  $^1\text{H}$  detection combined with radio frequency (RF) irradiation at  $^{13}\text{C}$  resonance lines. Such  $^1\text{H}$ – $^{13}\text{C}$  double-resonance studies were, however, of limited use for the solution of structural problems. Today, NMR instrumentation provides three, four, or more RF irradiation channels with interlocked frequencies, e.g., for  $^1\text{H}$ ,  $^2\text{H}$ ,  $^{13}\text{C}$ , and ( $^{15}\text{N}$  or  $^{31}\text{P}$ ), computer control for complex multipulse sequences and software for multidimensional data processing. The heteroatom resonance frequencies ( $X = ^{13}\text{C}$ ,  $^{15}\text{N}$ , etc.) could then be derived indirectly from the appropriate multidimensional spectrum. For  $^{13}\text{C}$  this produces a wealth of structural information without acquiring a single  $^{13}\text{C}$  free induction decay (FID) signal. Decision on whether to use direct or indirect detection depends on different factors, e.g., the problem under investigation, the amount of substance available, the spectrometer configuration, etc. Traditionally, direct  $^{13}\text{C}$  observation is most often used. It is this direct observation that is meant by the term  $^{13}\text{C}$  NMR.

## Experimental Requirements for $^{13}\text{C}$ NMR

### Spectrometer

All commercially produced FT-NMR spectrometers, irrespective of the magnetic field strength (25–226 MHz  $^{13}\text{C}$  at 100–900 MHz for  $^1\text{H}$ ), generally

meet the basic requirements for one- and multidimensional  $^{13}\text{C}$  NMR in liquids. The main interest in higher magnetic fields for  $^{13}\text{C}$  NMR spectra lies in the sensitivity gain that theoretically obeys  $B_0^{3/2}$  dependence. However, the actual improvement at very high fields may be less than expected for certain carbon atoms, e.g., carbonyl because of nonuniform excitation, decrease of  $T_2$  relaxation times, etc. A large variety of probes could be used for  $^{13}\text{C}$  detection – single, dual, and broadband probeheads, QNP probes (e.g.,  $^1\text{H}$ – $^{19}\text{F}$ – $^{31}\text{P}$ – $^{13}\text{C}$ ) with computer controlled switching among four nuclei at high sensitivity, etc. Sample tubes of 5 and 10 mm outer diameter are mainly used for direct detection. The best  $^{13}\text{C}$  sensitivity is reached with 10 mm probes with inner coil optimized for the  $^{13}\text{C}$  resonance frequency. Their use results in approximately threefold increase in signal-to-noise ratio (S/N) relative to the 5 mm probes, at the expense of somewhat lower resolution. However, for economic and practical reasons, 5 mm probes are most often used. For many experiments actively shielded Z-gradient coils are used. It should be, however, noted that most often they are optimized for the  $^1\text{H}$  resonance frequency and have a low sensitivity for direct  $^{13}\text{C}$  detection. In recent years, the so-called cold- or cryoprobes have been designed by the use of cryogenically cooled RF coil and preamplifier with up to four times higher sensitivity as compared to conventional room temperature coil probes. Multinuclear magic angle spinning (MAS) probes for both CP and high power decoupling experiments are applied for solid-state  $^{13}\text{C}$  NMR. Depending on the particular hardware a variety of different experiments could be performed. Most often used in the practice are 1D (dimensional) or 2D multipulse sequences, comprising proton and carbon pulses. The NMR spectrometers possess central

software packages for spectrometer control, data acquisition, and data processing. The latter could also be achieved on a separate computer, usually connected with the spectrometer through the network.

### Sample

Sample preparation for  $^{13}\text{C}$  NMR is very similar to that for  $^1\text{H}$  NMR. The standard sample volume is 0.4–0.6 ml for 5 mm, ~2.5 ml for 10 mm probes but may be as little as 0.04 ml in optional nanoprobe. Owing to the low sensitivity of  $^{13}\text{C}$ , the major requirement is to obtain as concentrated solution as possible in order to obtain a spectrum in as short time as possible. Obviously, if sample amount is unrestricted or solubility is low the use of larger sample tubes and correspondingly sample volumes becomes profitable. The minimum concentration requirements for a given sample and experiment depend mainly on the magnetic field strength and on the quality of the probe. For a relative molecular mass of less than 1000, 1D  $^{13}\text{C}$  NMR is routinely feasible for solutions at  $\sim 0.01 \text{ mol l}^{-1}$  in an overnight experiment. Approximately 1 h is needed for the measurement of the same sample on a 500 MHz spectrometer equipped with a cryogenically cooled probe. The suitability of the solvent to be used is dictated by the sample solubility at the measurement temperature. Recommended solvents are  $\text{CDCl}_3$ ,  $\text{DMSO-d}_6$ , and  $\text{D}_2\text{O}$ . A list of common solvents used in NMR work with their chemical shifts, multiplicities, dielectric constants, and liquid ranges are given in Table 1.

For  $^{13}\text{C}$  detection nondeuterated solvents could alternatively be used, especially for rare or very expensive solvents. In this case, a small capillary containing a deuterated substance, e.g., acetone- $\text{d}_6$ , is put into the sample tube. It provides the lock substance

**Table 1** Properties of some important solvents for NMR<sup>a</sup>

Solvent	Chemical shift $\delta_{\text{C}}$ (ppm)	Multiplicity due to $^1J_{\text{CD}}$	Liquid temperature range ( $^{\circ}\text{C}$ )	Dielectric constant
$\text{CCl}_4$	96.0	1	– 23 to 77	2.2
$\text{CS}_2$	192.3	1	– 112 to 46	2.6
$\text{CDCl}_3$	77.0	3	– 64 to 61	4.8
$\text{CD}_2\text{Cl}_2$	53.6	5	– 95 to 40	8.9
$\text{CDCl}_2\text{CDCl}_2$	75.5	3	– 44 to 146	8.2
THF- $\text{d}_8$	25.8, 67.8	5	– 108 to 66	7.6
Benzene- $\text{d}_6$	128.4	3	6 to 80	2.3
Pyridine- $\text{d}_5$	123.9, 135.9, 150.2	3	– 42 to 115	12.4
Acetone- $\text{d}_6$	30.0, 206.0	7	– 95 to 56	20.7
$\text{DMSO-d}_6$	39.6	7	19 to 189	46.7
Methanol- $\text{d}_4$	49.3	7	– 98 to 65	32.7
$\text{D}_2\text{O}$	–	–	0 to 100	78.5
TFA- $\text{d}$	114.5, 161.5 <sup>b</sup>	–	– 15 to 72	8.6

and assures the field-frequency stabilization. Usually, a small amount (0.03–0.05%) of tetramethylsilane (TMS) or of the less volatile hexamethyldisiloxane (HMDS, 2 ppm downfield from TMS), when working at elevated temperature, is added to the samples as reference. Often the signal of the deuterated solvent is used for referencing purposes (Table 1).

## Basic Characteristics of $^{13}\text{C}$ NMR

### Natural Abundance $^{13}\text{C}$ Spectra

Samples with natural  $^{13}\text{C}$  abundance are the usual case in routine  $^{13}\text{C}$  application. For a molecule with  $N$  carbon atoms, the  $^{13}\text{C}$  NMR spectrum usually appears as a mixture of  $N$  different spin systems  $\text{CH}_d\text{H}_l\text{H}_m, \dots, \text{H}_r$ , where the subscripts  $d, l, m, \dots, r$  refer to protons directly attached to, or separated by two or more bonds from, the carbon, respectively. Accordingly, the  $^{13}\text{C}$  spectrum is a superposition of  $N$  subspectra centered at the chemical shift  $\delta_i$  of the carbon nucleus  $i$  with  $i = 1, \dots, N$ . In case of molecular symmetry, two or more spin systems are alike and the intensities of the corresponding subspectra increase by a factor of two or more. In single-scan FT spectra, starting from thermal equilibrium (no NOE), all subspectra have the same overall intensity because the  $N$  spin systems are equally abundant. In multiscan FT spectra with coherent averaging (accumulation), intensities are generally different because the various carbons relax differently toward thermal equilibrium so that the  $z$ -magnetizations differ from carbon to carbon prior to each pulse. This is particularly pronounced for quaternary carbons that have comparatively long  $T_1$  relaxation times so that their signals are less intense or even lost in the noise compared to proton-connected ones.

### Coupled $^{13}\text{C}$ NMR Spectra

Coupled  $^{13}\text{C}$  NMR spectra are usually very complex and difficult to interpret. For a simple one-pulse experiment, each subspectrum is a symmetric multiplet centered at the chemical shift of the carbon nucleus (see Figure 1A). The multiplet structure is governed by the large one-bond  $^1J_{\text{CH}}$  value (100–320 Hz total range) and a number of small longer-range  $J_{\text{CH}}$  values mainly for  $^{13}\text{C}$ – $^{12}\text{C}$ –H and  $^{13}\text{C}$ – $^{12}\text{C}$ – $^{12}\text{C}$ –H fragments. Primary ( $\text{CH}_3$ ), secondary ( $\text{CH}_2$ ), and tertiary (CH) atoms can be distinguished by their multiplicities, since according to the first order- $(n+1)$  splitting rule they give rise to wide spaced quartets ( $n=3$ ), triplets ( $n=2$ ), and doublets ( $n=1$ ). Quaternary (C) carbons present singlets ( $n=0$ ) with low intensity. Each multiplet line is further split or broadened due to the longer-range couplings. Many

of these multiplets represent higher-order spectra despite which they often appear deceptively simple. Then a full spin-quantum mechanical analysis (e.g., with a computer program like LAOCOON) must be performed in order to derive the true  $\delta$  and  $J$  values. In many cases not only the  $^{13}\text{C}$  multiplet, but also the  $^1\text{H}$  NMR  $^{13}\text{C}$  satellite resonances must be analyzed. Further complications arise from the severe overlap of multiplets even in simple organic molecules.

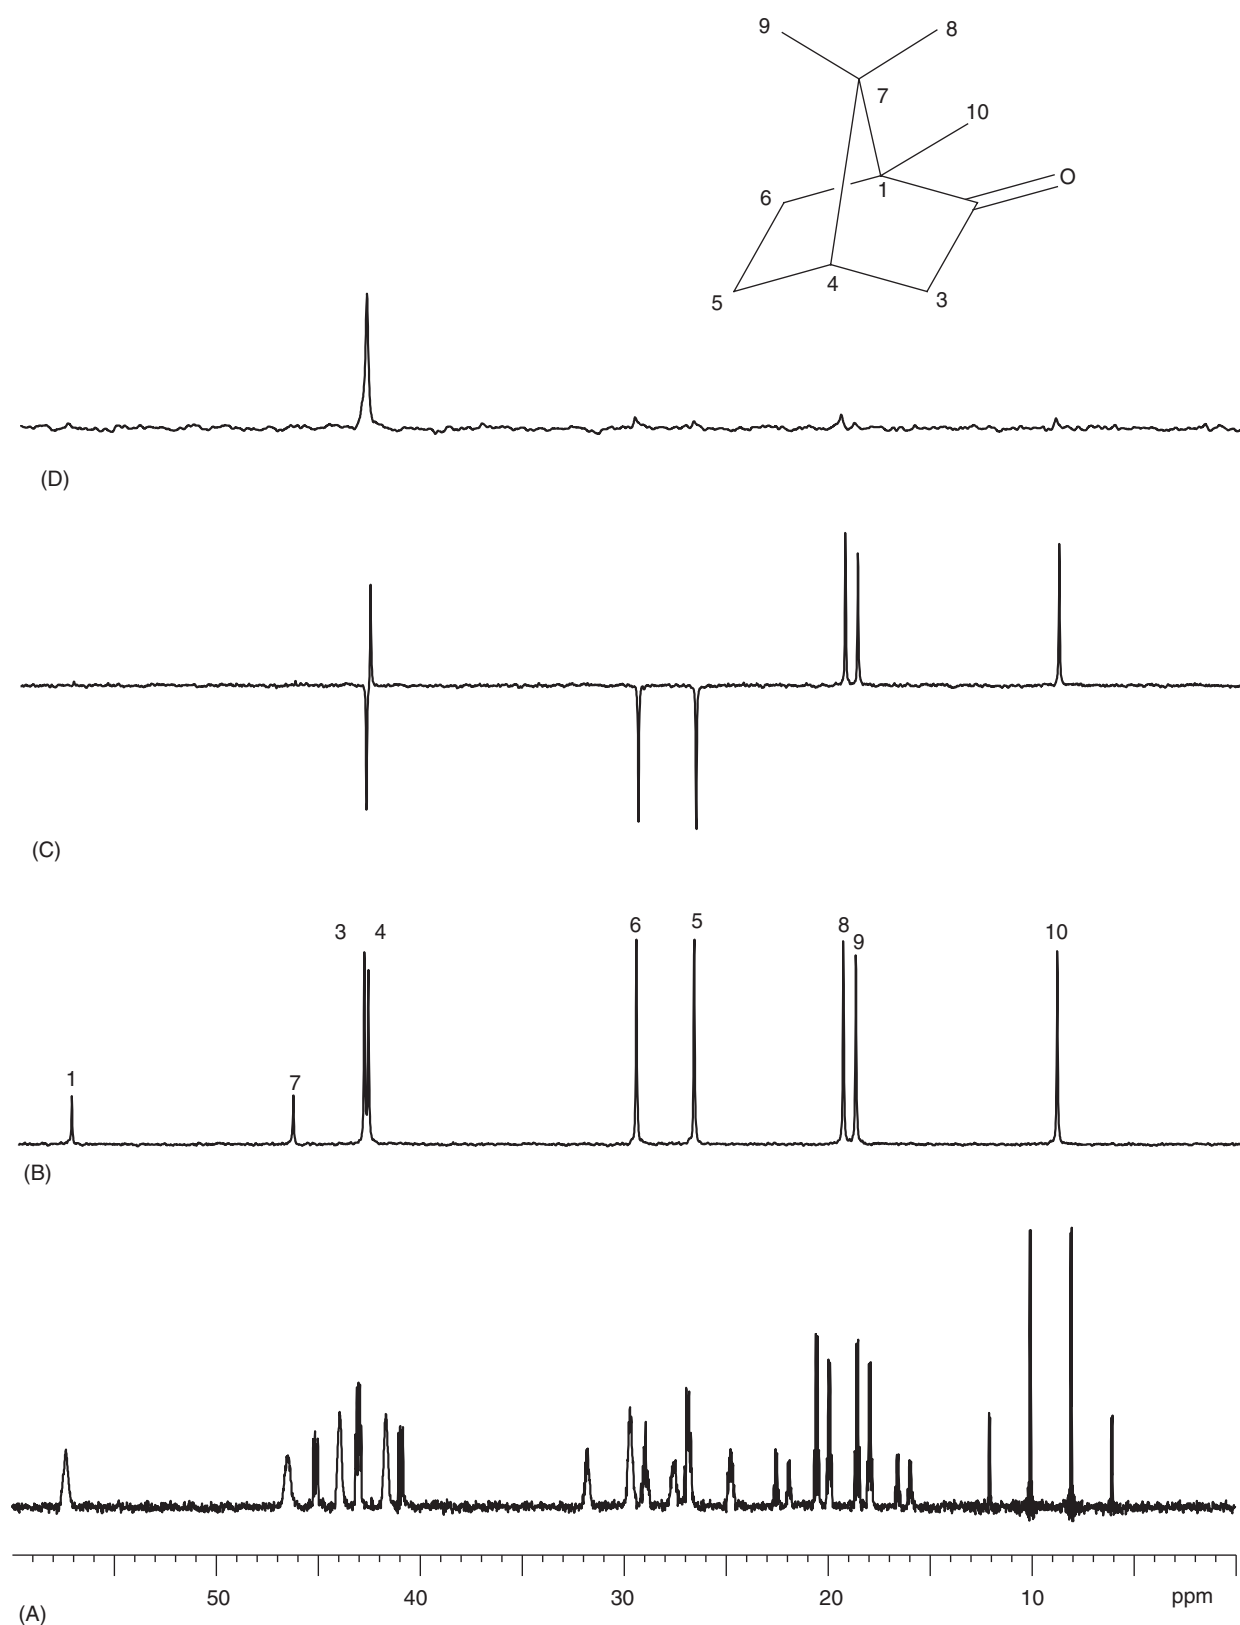

Another serious drawback of the  $^{13}\text{C}$ -coupled spectra is the intrinsic low S/N ratio. The splitting in many components leads to a substantial decrease of the maximum line heights as compared with uncoupled lines. This leads to a dramatic increase in measuring time of at least a factor of 10, but usually much more. The gated-decoupling technique is most often used for direct measurement of coupled  $^{13}\text{C}$  NMR spectra since applying it up to a threefold gain in carbon sensitivity from the build-up of NOE could be achieved.

In summary, coupled  $^{13}\text{C}$  NMR spectra are only occasionally directly measured. The tendency is to measure decoupled spectra and to retrieve the coupling information by well-designed more or less sophisticated 1D or 2D pulse sequences in a more efficient and timesaving way.

### $^1\text{H}$ -Decoupled $^{13}\text{C}$ Spectra

A considerable simplification of the appearance of the  $^{13}\text{C}$  spectra (see Figure 1B), is achieved by application of broadband (BB) decoupling – the multitude of lines concentrate to a number of single sharp peaks with high intensities, each at the chemical shift  $\delta$  of the chemically nonequivalent  $^{13}\text{C}$  atoms. The technique effectively eliminates all coupling constants between the proton and the carbon nuclei. The spectra are usually denoted as  $^{13}\text{C}\text{--}\{^1\text{H}\}$ , the nucleus outside the brackets being observed while that inside the brackets is simultaneously decoupled. Apart from the increase in S/N due to the collapse of the multiplet structure, proton decoupling additionally adds to the signal intensity due to the nuclear Overhauser effect (NOE), which in favorable cases can produce an almost threefold increase over and above that produced by the collapse of the fine structure. The analysis of these spectra is relatively easy. Determination of the values of the chemical shifts only is in striking contrast to the embarrassment by the examination of the complex structure of  $^1\text{H}$ -coupled spectra. The high sensitivity and the easy interpretation are the two main reasons why decoupled  $^{13}\text{C}$  NMR spectra are most widely used. Furthermore, signal separation in  $^{13}\text{C}$  NMR is much better than in  $^1\text{H}$  NMR owing to the considerably

**Figure 1**  $^{13}\text{C}$  NMR spectra of camphor – aliphatic region with assignment (the carbonyl resonance at 220 ppm is not shown): (A)  $^1\text{H}$ -coupled  $^{13}\text{C}$  NMR spectrum; (B)  $^1\text{H}$  BB-decoupled  $^{13}\text{C}$  NMR spectrum: nine aliphatic carbons can be readily determined from the observed nine single-line resonances; (C) DEPT-135: CH<sub>3</sub> and CH pointing up, CH<sub>2</sub> – down, quaternary are missing; (D) DEPT-90: only CH signals with significant intensity.

larger  $^{13}\text{C}$  shift range, as accidental signal coincidence is seen less often.

Different experimental schemes could be used for heteronuclear BB decoupling. Older instruments used to apply Pnd – the decoupler is set in the center of the proton region and modulated using a ‘noise generator’ with a bandwidth wide enough to cover the complete proton region (e.g., 1000 Hz at 2.4 T). This is equivalent to simultaneous irradiation of every proton frequency. Composite-pulse decoupling (CPD) is the method of choice in advanced instruments since it requires less power and sample heating could be kept to a minimum. Important characteristics of the CPD sequences are the bandwidth – the range of proton offsets that can be decoupled for a given  $^1\text{H}$  carrier frequency – and the CPD quality, indicated by the presence or absence of weak side band signals, residual broadening, or fine structure in the decoupled  $^{13}\text{C}$  peaks. WALTZ-16 scheme (wide-band alternating-phase low-power technique for zero-residual splitting) with composite pulse element  $90_x^\circ\text{--}180_x^\circ\text{--}270_x^\circ$  is commonly employed for proton-decoupled  $^{13}\text{C}$  spectra because of its optimum performance – sufficient bandwidth and good quality. For decoupling of the full carbon range,  $^1\text{H}\text{--}\{^{13}\text{C}\}$ , as, e.g., needed in inverse 2D methods, the GARP sequence (globally optimized alternating-phase rectangular pulses) is used because of its large bandwidth, with some compromise of the decoupling quality. For more special applications many more different CPD sequences have been designed.

### Multiplicity-Edited $^{13}\text{C}$ NMR Spectra

Against the obvious benefits in decoupled spectra – simplicity and sensitivity – is the loss of all coupling information that is often needed for assignment purposes. Especially valuable is the multiplicity of a carbon atom, indicating the number  $n$  of its directly connected protons. The most efficient methods to recover this coupling information rely on encoding of the carbon multiplicity in the signal sign and intensity. Two pulse sequences and their modifications are most often applied. Historically first was the so-called APT, based on the use of a  $J$ -modulated heteronuclear spin-echo. More advanced is the DEPT sequence, characterized by editing properties with negligible dependence on the  $^1J_{\text{CH}}$  value and signal enhancement by PT. The observed  $^{13}\text{C}$  signal intensities are proportional to  $\cos^n \theta$ , where  $n$  is the number of the attached protons and  $\theta$  the third proton pulse in the DEPT sequence. The collection of three spectra with  $\theta = 45^\circ$ ,  $90^\circ$ , and  $135^\circ$  is the starting point for the determination of the carbon multiplicities. Depending on their multiplicities the carbon atoms

**Table 2** Signs of multiplet resonances in DEPT spectra with different  $\theta$

Carbon type	DEPT-45	DEPT-90	DEPT-135
$\text{CH}_3$	+	0	+
$\text{CH}_2$	+	0	–
CH	+	+	+
C	0	0	0

produce positive, negative, or zero signal intensities for these angles, the type of the responses is summarized in Table 2. In principle, decomposition into  $\text{CH}$ ,  $\text{CH}_2$ , and  $\text{CH}_3$  subspectra can be produced by a linear combination of the three spectra. More often, however, the multiplicities are determined mainly on base of the signal signs in the DEPT-135 spectrum (see Figure 1C). Methyl and methine carbons show positive signals, methylene atoms give negative signals, whereas quaternary carbons do not appear.  $\text{CH}_3$  and CH signals can be usually distinguished by chemical shift arguments, but sure proof is obtained from the DEPT-90 spectrum (see Figure 1D), containing signals with considerable intensity only for the methine atoms.

### NOE Enhancement

Under conditions of proton decoupling the enhancement of the carbon signals is normally greater than it would be expected from the collapse of the multiplet structure into a single line due to perturbation of the spin state populations from their equilibrium states. This additional enhancement is known as the nuclear Overhauser effect or the NOE factor  $\eta$ . It is quantitatively expressed by  $I = (1 + \eta)I_0$ , where  $I$  and  $I_0$  are the total  $^{13}\text{C}$  line intensities with and without  $^1\text{H}$  decoupling. The intensity gain  $\eta$  approaches one-half the quotient of the  $^1\text{H}$  and  $^{13}\text{C}$  magnetogyric ratios,  $\gamma_{\text{H}}/2\gamma_{\text{C}} = 1.98$  for isotropically reorienting small organic molecules in nonviscous solvents under C–H internuclear dipole–dipole relaxation. It should be noted that  $\eta$  could be quite different for each individual carbon atom and is an additional reason for their different intensities in decoupled spectra. As a relaxational phenomenon the NOE builds up and disappears with a time constant equal to the spin-lattice relaxation time  $T_1$ . This behavior is opposite to the process of decoupling that disappears instantly when the decoupler is turned off and provides the basis of the so-called gated decoupling technique. By using switching of the decoupler power the two effects – coupling and NOE – can be separately observed. Two schemes are more widely used, which are:

- Gated decoupling: coupled spectra with NOE for sensitivity enhancement – with the decoupler turned on only during the relaxation time.

- Inversed gated decoupling: decoupled spectra without the NOE for determination of  $\eta$  or quantitative analysis – with the decoupler turned on only during the acquisition time.

## Spectrum–Structure Relationship

### $^{13}\text{C}$ Chemical Shifts

The ‘normal’ range of  $^{13}\text{C}$  chemical shifts is  $-30$  to  $230\delta$ , so that the spread of chemical shifts is  $\sim 20$  times that of the proton. Figure 2 shows typical chemical shift ranges for a number of common carbon environments. There is an overall similarity to the proton chemical shifts. What is similar for both nuclei is the pronounced dependence on the hybridization and the order of shielding – aldehydes, olefins and aromatics, substituted alkanes to alkanes. However, the analogy must not be carried too far. For example, although shielding caused by exchange with first row atoms follows the order of the substituent electronegativities, this is not the case for chlorine, bromine, and iodine, in which upfield shifts have been found. This ‘heavy atom’ effect has no

counterpart in proton chemical shifts. Furthermore, the effect of the substituents on  $^{13}\text{C}$  shifts is not confined to the nearest atom ( $\alpha$ ), as in proton chemical shifts, but must be evaluated for substituents two ( $\beta$ ), three ( $\gamma$ ), and four ( $\delta$ ) bonds from the carbon atom considered. It should be noted that the substitution in  $\alpha$ -,  $\beta$ -, and  $\gamma$ -position generally deshields the carbon but one in  $\gamma$ -position shields. The  $\gamma$ -effect has been interpreted as a steric shift and is of importance for distinguishing *Z/E* and *gauche/anti* stereoisomers. The effects of  $\delta$ - or further positions are usually small (less than 3 ppm), but these long-range effects ( $\gamma$ ,  $\delta$ , etc.) may be large in cyclic compounds, depending on the distance of the substituent from the respective carbon. Additionally, many other shift effects such as electric field, isotope, solvent may reach, in special cases, a magnitude of several ppm.

The various factors contributing to the shielding generally combine in a complex manner. An outstanding feature of  $^{13}\text{C}$  chemical shifts is the finding that substituent contributions are reasonably additive, especially when they do not directly interact. This allows substituent parameters for different classes of organic compounds to be determined and

Figure 2  $^{13}\text{C}$  chemical shift correlation chart for common organic compounds.

used for signal assignments. As an example empirically determined effects (substituent-induced chemical shifts, SCS) for alkanes are presented in Table 3. Unsaturated carbon shifts are generally easier to interpret because they primarily depend on the local p-electron density, which is mainly governed by mesomeric effects (see Table 4). This is especially straightforward for monosubstituted benzene derivatives (see Table 5). The SCS values for carbons in *para*-positions of benzene rings can be used for determination of Hammett  $\sigma$ -constants of rare substituents. A number of empirical parameters and additivity schemes can be found in the literature for different carbon environments. Recently, many standalone or web-based computer programs offer different schemes for prediction of carbon chemical shifts, which rely on empirically based increments,

on quantum chemistry calculations, on library search with or without use of artificial neural networks, etc.

Not only the isotropic chemical shift but also the anisotropy of the chemical shielding (CSA) tensor of the  $^{13}\text{C}$  nucleus is another unique NMR parameter that could be generally measured. Such a tensor is a probe to the electron density distribution around the nucleus and provides structural information that is very difficult to obtain by other means.

### $^{13}\text{C}$ Coupling Constants

Coupling constants to  $^{13}\text{C}$  are generally tedious to measure because of the low natural abundance of the carbon nucleus. Depending on the subject under investigation as well as on the availability of substance and instrumentation different experimental schemes could be most practical. Often, the presence or absence of a coupling above certain threshold (e.g., 2 Hz) could be sufficient for solving the problem. Commonly used methods are the following:

- inspection of the  $^{13}\text{C}$  satellites in the  $^1\text{H}$  spectrum;
- $^{13}\text{C}$  NMR spectra under gated decoupling conditions;
- various selective and nonselective 2D methods with direct or inverse detection (CH-*J*-resolved, HSQC, HMBC, etc.)

Coupling to abundant nuclei ( $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^{19}\text{F}$ ) is most easily detected. Measurement of C-C and of heteronuclear coupling constants to low abundant nuclei is still a time consuming task, even in modern

spectrometers with high sensitivity unless  $^{13}\text{C}$  or heteroatom enrichment is carried out.

In dealing with heteronuclear couplings the general relationship  ${}^nJ_{\text{CX}} = \gamma_{\text{C}} \cdot \gamma_{\text{X}} \cdot {}^nK_{\text{CX}}$  can be used.  ${}^nK_{\text{CX}}$  depends on the electron density distribution along the  $n$  bonds. This provides the basis for an estimation of  $J$  values in situations where bonding is expected to change little with variation in X, e.g., when D is substituted for H. Tables 6–8 show an overview of representative carbon couplings.

One-bond  ${}^1J_{\text{CH}}$  couplings are of some theoretical interest, as they seem to be directly proportional to the fraction of s-character ( $\rho$ ) of the C–H bond ( ${}^1J_{\text{CH}} \sim 500\rho$ ). The couplings in methane ( $\text{sp}^3$ ),

ethylene ( $\text{sp}^2$ ), and acetylene ( $\text{sp}$ ) agree well with this prediction. Observed coupling of 160 Hz strongly supports the trigonally hybridized model for cyclopropane. This simple and very useful relationship is, however, strictly valid only for hydrocarbons and compounds without strongly perturbing substituents. In substituted methanes the C–H coupling changes considerably with the introduction of polar substituents and this is not primarily due to any change in the carbon atom hybridization. The substituent effects are reasonably additive and may be used to estimate C–H couplings in any multisubstituted compound. In summary, these  ${}^1J_{\text{CH}}$  couplings are of diagnostic use and can be utilized as routinely as HH couplings to provide structural information. Additionally, they are relatively easily measured.

Geminal and vicinal couplings have a similar general pattern to the analogous H–H coupling, being somewhat smaller in magnitude – the relation  ${}^{2,3}J_{\text{CH}} = (0.6 \pm 0.1){}^{2,3}J_{\text{HH}}$  usually holds for cases of comparable binding. Especially useful in aliphatic compounds is the Karplus-like dependence of the vicinal couplings. For carbon and proton in synclinal or antiperiplanar position one measures couplings  $\sim 2$  and 9 Hz, respectively, whereas in freely rotating fragments a value in the range of 4 Hz should be expected. Of special diagnostic value in alkenes and aromatics is the rule that  ${}^3J_{\text{CH}} > {}^2J_{\text{CH}}$ .

One-bond C–C coupling, as  ${}^1J_{\text{CH}}$ , correlates with the s-character of both carbons according to:  ${}^1J_{\text{CC}} \sim 730s_1 \cdot s_2 - 17$ .  ${}^2J_{\text{CC}}$  values are usually smaller than  ${}^3J_{\text{CC}}$ . Larger  ${}^2J_{\text{CC}}$  values are observed if the carbons have high s-character (e.g., ethynes) or when an electron deficient carbon is involved. C–C vicinal coupling constants behave in a similar way as  ${}^3J_{\text{CH}}$  and  ${}^3J_{\text{HH}}$ . In fact, available data indicate that substitution of a hydrogen by carbon reduces  ${}^3J$  by a factor of  $c = 0.6\text{--}0.8$ , i.e.,  ${}^3J_{\text{CC}} = c \cdot {}^3J_{\text{CH}} = c^2 \cdot {}^3J_{\text{HH}}$ .

$^{13}\text{C}$ – $^{15}\text{N}$  coupling constants have smaller magnitude than their C–H counterparts because of the low magnetogyric ratio of  $^{15}\text{N}$ . One-bond couplings may be estimated according to  $|{}^1J_{\text{CN}}| = 125s_{\text{C}}s_{\text{N}}$ , where  $s_{\text{C}}$

and  $s_N$  represent the  $s$ -character of the bonding partners. The signs of  $^nJ_{CN}$  are usually opposite to the signs of the C–H and H–H couplings because of the negative magnetogyric ratio of  $^{15}\text{N}$ .

$^{13}\text{C}$ – $^{19}\text{F}$  coupling constants are larger than their C–H counterparts, e.g., 271 and 235 for  $\text{CH}_3\text{CF}_3$  and  $\text{CF}_2\text{H}_2$ .

An illustrative example of  $^{13}\text{C}$ – $^{31}\text{P}$  couplings is provided for  $\text{CH}_3\text{CH}_2\text{PO}(\text{OCH}_2\text{CH}_3)_2$ :  $^1J_{\text{CP}} = 143\text{ Hz}$ ;  $^2J_{\text{CP}}$  (CCP) = 7.1 Hz;  $^2J_{\text{CP}}$  (COP) = 6.9 Hz;  $^3J_{\text{CP}}$  (CCOP) = 6.2 Hz.

### Spin–Lattice Relaxation Times $T_1$

$^{13}\text{C}$   $T_1$  values are often measured under conditions of BB decoupling using the inversion–recovery (IR) pulse sequence. A single line for each carbon atom is collected with an intensity, following the law:  $I = I_0[1 - 2\exp(-\tau/T_1)]$  for ideal pulses and sufficiently long relaxation delays. In practice, intensities are fitted to the expression  $A - B\exp(-\tau/T_1)$  in order to avoid systematic errors due to imprecise  $I_0$  values, pulse imperfections, and offset effects. Determination of  $I$  is often more accurate if lines are artificially broadened during FT data processing. In medium-sized organic molecules (10–50 carbon atoms)  $T_1$  values are typically in the range 0.1–15 s for proton-bearing carbon atoms. The  $T_1$  values of quaternary carbons are much longer.

A number of mechanisms are known to contribute to spin–lattice relaxation in a molecule: dipole–dipole, spin–rotation, quadrupolar, scalar, and CSA, each associated with a corresponding relaxation rate. Analytical interest focuses only on the internuclear C–H dipole–dipole relaxation with a rate  $R_{\text{IDD}} = 1/T_{\text{IDD}} = (\eta/1.988)(1/T_1)$ , which is proportional to the inverse sixth power of the carbon–proton distance  $r_{\text{CH}}$ , and depends on the rotational and internal molecular motion. For medium-sized molecules of nearly spherical shape (isotropic molecular reorientation) in solvents of low viscosity the condition of extreme narrowing holds, i.e.  $\omega_C\tau_c \ll 1$  for all Larmor frequencies  $\omega_C$ , and therefore  $R_1 = AN\tau_c$ . The correlation time  $\tau_c$  is a measure of the velocity of the molecule's rotational diffusion jumps. For  $N$  nearest protons within a distance  $r_{\text{CH}}$  the quantity  $A$  takes the form  $A = (b\gamma_C\gamma_H/2\pi)^2/r_{\text{CH}}^6$  and becomes  $3.56 \times 10^{10}\text{ s}^{-2}$  for  $r_{\text{CH}} = 109\text{ pm}$ .

If proton-bearing carbons have  $T_1$  values less than 20 s the dipole–dipole term predominates and  $T_{\text{IDD}}$  can be set equal to  $T_1$ . The  $N$  dependence strictly holds only if CH and  $\text{CH}_2$  are part of the rigid backbone of the molecule, then their motional characteristics are alike.  $\text{CH}_3$  groups have usually additional rotation about their symmetry axis with little or no hindrance, so that their overall motion is quite

different and the simple  $N$  law given above does not hold.  $T_1$  values in the rigid backbone of a molecule generally decrease with molecular size since  $\tau_c$  increases with size. The rule of thumb is that  $\tau_c$  (in ps) is equal to their molecular weight (in Da) for globular molecules in water. In practice, nonspherical molecules with conformational flexibilities are more commonly met than rigid spheres. For instance, segmental mobility in  $n$ -alkyl side chains produce pronounced differences in relaxation rates. A classic example is found in 1-substituted  $n$ -alkanes, where the substituent ‘anchors’ the end of the molecule due to a high moment of inertia in the case of Br or to hydrogen bonding for substitution with a hydroxyl group. This reflects in the  $T_1$  values, measured for  $n$ -decanes that are shorter the slower the effective motion of each individual  $\text{CH}_2$  moiety occurs (in s):

	X - $\text{CH}_2$ - $\text{CH}_2$ - $(\text{CH}_2)_3$ - $\text{CH}_2$ - $\text{CH}_2$ - $\text{CH}_2$ - $\text{CH}_2$ - $\text{CH}_2$							
X = H	8.7	6.6		4.4	5.0	5.7	6.6	8.7
X = Br	2.8	2.7	2.0	2.0	2.0	3.1	3.9	5.3
X = OH	0.7	0.8	0.8	0.8	1.1	1.6	2.1	3.1

Rotational diffusion jumps around a parallel (long) axis in rod-shaped rigid molecules turn up faster than those with respect to any vertical axis. Consequently, the effective correlation time for the C–H vector reorientation, responsible for the relaxation rate of the target  $^{13}\text{C}$  nucleus, depends on the angle between the C–H vector and the parallel axis. The detailed treatment is quite complex but the trends become evident from the  $T_1$  values in molecules like phenylethyne and its shape analogous derivatives (Table 9). Depending on the solvent the observed  $T_1$  values differ up to a factor of 2.5 that is quite substantial for molecules of that size. The *para*- and the ethyne-carbons have shorter  $T_1$  values because their C–H reorientation is mainly caused by slow rotational jumps about the vertical axis.  $T_1$  values for *ortho*- and *meta*-carbons are larger due to the further fast rotational diffusion around the parallel axis. The pronounced dependence of the relaxation rates on solvent viscosity is clearly revealed from the data in Table 9. Additionally, the effects of intermolecular interaction in phenylpropylene, of hydrogen bonding in phenylethyne, and of stacking due to electric dipole–dipole interactions in benzonitrile could be followed.

### $^{13}\text{C}$ Line Widths

The  $^{13}\text{C}$  signal, as generated by a single pulse, nearly follows the exponential decay law  $\exp(-t/T_2^*)$  as is

**Table 9** Solvent dependence of  $^{13}\text{C}$   $T_1$  relaxation times (in s)<sup>a</sup>

Solvent	$\text{Ph}-\text{C}\equiv\text{CH}$				$\text{Ph}-\text{C}\equiv\text{C}-\text{CH}_3$			$\text{Ph}-\text{C}\equiv\text{N}$		
	Ortho	Meta	Para	$\equiv\text{CH}$	Ortho	Meta	Para	Ortho	Meta	Para
$\text{Ph}-\text{C}\equiv\text{CH}$	12.8	12.8	8.7	8.8	8.4	8.4	4.2	10.4	11.6	6.6

<sup>a</sup> 22.6 MHz  $^{13}\text{C}$  measurements at 303 K. Concentrations are given in parentheses; 'infin. dil.' stands for extrapolation to infinite dilution.

<sup>b</sup>  $^{13}\text{C}$  lines not resolved for *meta*- and *para*-carbons.

<sup>c</sup> Solvent viscosities: 0.93 cP for phenylethyne and 4.05 cP for  $\text{OP}(\text{N}(\text{CH}_3)_2)_3$  at 303 K; 0.9 cP for cyclohexane at 298 K.

common in NMR. Accordingly, the  $^{13}\text{C}$  resonance line approximates the Lorentzian shape with a full half-width of  $\Delta\nu = 1/(\pi T_2^*)$ . The broadening parameter  $T_2^*$  is a sum of both natural, namely spin-spin relaxation and anisotropy broadening, and instrumental contributions. The latter usually dominates, most notably due to magnetic field inhomogeneity, unresolved long-range couplings, and/or residual linewidth effects from broadband decoupling. It is often overlooked that molecular motion may be not fast enough, e.g., solutions of large biomolecules or polymers, for complete averaging of the large  $^{13}\text{C}$  chemical shift anisotropies to be achieved. In such a case anisotropy broadening may become substantial. This has in fact been observed and may be expected to be more important for  $^{13}\text{C}$  NMR at very high static magnetic fields.

In a multiscan pulse experiment with pulse spacing,  $\tau$ , the first pulse may produce maximum signal intensity  $I_0$  of each  $^{13}\text{C}$  resonance line. The intensity  $I$  after the second pulse is a function of  $\tau$  and generally comes out smaller if  $\tau < 5T_1^*$ , the ratio  $I/I_0$  being equal to  $1 - \exp(-\tau/T_1)$ , where  $T_1$  is the spin-lattice relaxation time. For pulse intervals greater than  $5T_1$ , the ratio  $I/I_0$  is essentially unity. Experimental  $^{13}\text{C}$   $T_1$  values vary from  $\sim 0.1$  to 300 s for organic molecules. Large variations for each individual carbon site in a given molecule could occur. In neat phenylethyne this varies from  $\sim 10$  s for the proton-bearing carbons to 100 s for quaternary carbons, while in *n*-decanol values from 3.1 s at the aliphatic-end carbon down to 0.7 s for the O-end carbon are measured. An important analytical aspect of the large  $T_1$  variations in a given molecule is that line intensities do not strictly reflect the number of chemically equivalent carbon atoms. These differences can be usually analytically explored for distinguishing of proton-bearing and quaternary carbons,

provided the latter have intensities above the noise level. For assuring their appearance, excitation by the so-called Ernst angle, an average optimum pulse angle, instead of the  $90^\circ$  pulse, is usually exerted. For routine applications  $30^\circ$  pulses with an interpulse delay of 2 s are most common.

### $^{13}\text{C}$ Spectra for Structure Elucidation

Routinely 1D decoupled and multiplicity-edited spectra are the primary source of  $^{13}\text{C}$  NMR spectral information. Combined with the available  $^1\text{H}$  NMR spectral information, an overall picture of the number of structural elements in the molecule is obtained. It could be used for structure elucidation and/or spectral assignments. Further spectroscopic information (mass and/or optical spectra) or other knowledge (compound class, synthesis routes, etc.) facilitates generation of guess structures. More or less luckily this could be done from NMR data alone, even in absence of additional data. The number of the carbon and proton atoms in the molecule could often be reliably assumed. Equivalence by accident can be discarded by inspection of the proton and carbon spectra, which are usually unlike in contrast to cases with equivalence by symmetry. Use of special information, temperature dependence of spectral parameters, exchange line broadening, segmental motion and/or anisotropic rotation of molecules, solvent and dilution effects, etc., can have additional diagnostic value. Knowledge of established relationships between NMR parameters – chemical shifts, coupling constants, relaxation times – and molecular structure are of prime importance in the next step – unambiguous assignment of as many as possible carbon and proton signals based on shift and proton coupling arguments. Because of the great detail in the spectra, this can be quite laborious. Fortunately,

extensive support by an increasing number of powerful spectroscopic tools is provided, offered both by instrument producers and chemistry software houses. These can easily be used on- or offline since virtually every NMR spectrometer is now linked to a workstation and hence to local and far-reaching computer networks. Assignments may be achieved on the bases of one or more of the following approaches:

- $^{13}\text{C}$  spectral similarity search in libraries – printed collection or a computer database with software for storage, retrieval, and search. Libraries may be homemade or commercially available and accessed in home or via the public network.
- Generation of trial structures and substructures possibly constrained by known substructures.
- Comparison of observed  $^{13}\text{C}$  chemical shifts with predicted parameters in trial (sub)structures. Predictions can be made using correlation charts, empirically derived additivity relationships (e.g., HOSE code), or theoretical calculations at different levels of precision (including *ab initio*). In recent years, artificial neural networks are more and more applied for prediction.

At the end of this step typically one or more trial structures survive, some of the assignments still remain uncertain. This necessitates additional experiments for establishing and verification of C–H connectivities along the carbon chain. More often a combination of proton-detected gradient accelerated 2D correlation experiments (or their selective 1D versions) is applied because of their higher sensitivity and shorter measuring times. Most important sequences are: HSQC (HMQC) and HMBC – for establishing one- and multiple-bond C–H correlations. They assist structure unfolding and afford sure signal assignment of one nucleus provided the assignment of the other is certain. Complete NMR analysis generally includes additional COSY, NOESY (for establishing through-bond and through-space H–H connectivities) and/or TOCSY (as a proof of a common H–H coupling pathway) experiments.

Due to its inherent insensitivity the important direct 2D experiment for tracing of the carbon skeleton – INADEQUATE (incredible natural abundance double quantum transfer experiment), based on measurement of doubly  $^{13}\text{C}$ -labeled species needs, unless  $^{13}\text{C}$  enriched, a large quantity of the compound under investigation. In favorable cases the proton-detected analogue ADEQUATE could be applied.

Despite the fact that a totally automated structure elucidation tool still remains a vision for chemists and spectroscopists and is a declared object for

software developers, in recent years tremendous progress toward automation of that process has been achieved. By analogy to the intuitive approach so far applied, a few software tools have been designed that allow interactive structure elucidation of an unknown compound, e.g., using  $^1\text{H}$ ,  $^{13}\text{C}$ , DEPT, COSY, HSQC, and HMBC spectra.

### Isotopic Enrichment

Along with the improvement in  $^{13}\text{C}$  detection techniques,  $^{13}\text{C}$  labeling developed into an excellent tool for structure analysis not only of small organic molecules (determination of  $^{13}\text{C}$  coupling constants and connectivities) but also of proteins and oligonucleotides and for elucidation of reaction pathways in biosynthesis. Today, a huge variety of labeling patterns are achievable, among them complete, block, site, stochastic, exchange, metabolic, and residue-specific labeling. A common approach is to grow microorganisms on a nutrient medium containing  $^{13}\text{C}$ -labeling precursors. In order to ascertain where the precursor has been incorporated into the target molecule it is mandatory to assign each  $^{13}\text{C}$  NMR signal. Depending on the system studied and on the acceptable degree of spectral complexity, a choice of the type of precursor, of the degree of enrichment, and of the number and position of the  $^{13}\text{C}$  label(s) in the precursor molecule has to be made. For example, experiments with doubly labeled compounds such as  $^{13}\text{CH}_3^{13}\text{COONa}$ , a nutrient of frequent use, allows the follow-up of the fate of a bond rather than of an individual carbon as for singly labeled acetates. However, use of highly enriched species may lead to complicated  $^{13}\text{C}$  spectra due to multiple C–C coupling and/or strong coupling effects. A simple remedy in practice is the dilution of one part in two to five parts of unlabelled sodium acetate that renders C–C couplings between the doubly labeled acetate groups negligible.

### Solid-State $^{13}\text{C}$ NMR

$^{13}\text{C}$  NMR studies of polycrystalline or glassy organic materials are now possible on a routine basis. Here, the low natural  $^{13}\text{C}$  abundance becomes an advantage rather than a drawback since dipolar broadening of the target  $^{13}\text{C}$  nuclei due to protons can be removed by high-power  $^1\text{H}$  decoupling while that due to other carbons is negligible because of the underlying inverse-cubic distance dependence of dipolar interactions. Another major obstacle, namely the long  $^{13}\text{C}$   $T_1$  values in solids and hence the long relaxation delays needed for signal averaging, is overcome with the H–C CP technique. As a result,  $^{13}\text{C}$

signal enhancement of 3.98 ( $\gamma_{\text{H}}/\gamma_{\text{C}}$ ) could be gained for each scan, so that more FIDs can be collected in a given time because the faster relaxing protons govern the recovery to equilibrium. This applies both to proton bearing and to quaternary carbons since the underlying dipolar interactions have through-space character in contrast to that mediated by the electrons of the C–H bond scalar interactions.

$^{13}\text{C}$  CP spectra with high-power  $^1\text{H}$  decoupling exhibit broad resonance lines which reflect the CSA of each  $^{13}\text{C}$  nucleus. For example, in poly hydroxybutyrate ( $-\text{O}-\text{CH}(\text{CH}_3)-\text{CH}_2-\text{CO}-$ ) $_n$ , the spectrum at 50.3 MHz consists of two broad lines that span over the range from  $-50$  to  $280$  ppm. The CO resonance shows a CSA pattern and extends from  $\sim 120$  to  $260$  ppm. The patterns completely overlap for the aliphatic carbons. These resonances can be made to collapse into relatively sharp single lines by rapid rotation of the sample container about an axis being tilted by  $54^\circ 44'$  with respect to the  $B_0$  direction (MAS). For spinning at  $\sim 4$  kHz, a sharp  $^{13}\text{C}$  resonance line is observed for each of the four carbon types. For spinning rates of  $\sim 600$  Hz, many sharp spinning side bands show up. Their intensities map the CSA line profile. Today, CPMAS  $^{13}\text{C}$  NMR is a standard tool for the study of polymers and other organic materials because high-resolution  $^{13}\text{C}$  spectra can be obtained for insoluble substances. A widely used application is the differentiation of polymorphic forms in the pharmaceutical industry (e.g., aspirin). When spinning cannot be set to a high enough rate for complete collapse, e.g., at very high fields, suppression techniques such as TOSS (total suppression of side bands) can be applied for spectrum simplification. In recent years many new  $^{13}\text{C}$  solid-state applications have evolved.

## Quantitative Analysis

Quantitative NMR determination ( $^{13}\text{C}$  at the order of 1%) is an analytically important though troublesome topic in NMR in general. In principle, the free induction decay (FID) height  $F_0$  immediately after a single RF pulse is a faithful relative measure of the molecular concentration. It can easily be determined in the recorded FID for single-line spectra. For analytical purposes, the single-line  $F_0$  values need to be compared for several samples that require the changing of sample tubes. Care has to be taken that instrumental conditions are not affected, e.g., the tuning of the receiver coil as caused by a different dielectric constant of the bulk sample. In multiline spectra, this usually poses no problem since relative intensities are measured in the same sample. Here,

however, individual  $F_0$  values are not accessible in the FID so that the FT or a method for nonlinear spectral analysis such as linear prediction (LP), maximum entropy method (MEM), or Bayesian analysis must be applied. Then, intensities  $F_0$  are obtained from the areas (not from the height!) under the resonance lines. Practical spectral analysis, unfortunately, is prone to error, mostly because of FID truncation effects and inaccurate digital integration (bad baseline, insufficient number of data points per line, poor integration routine).

In the case of  $^{13}\text{C}$  NMR there are specific advantages and disadvantages. Advantageous are the  $^1\text{H}$ -decoupled spectra since there is only one line for each carbon. In not too crowded spectral regions, Lorentzian line-broadening can be applied during data processing that alleviates truncation and integration artifacts. Regions with closely spaced lines may be selectively subjected to nonlinear spectral analysis (LP, MEM, Bayesian). The main disadvantages are the low sensitivity and the pronounced differences in  $^{13}\text{C}$  spin-lattice relaxation times and NOE factors within the same molecule and their different susceptibility to the molecular environment, e.g., when the temperature or solvent is changed. Common solutions comprise careful and precise adjustment of the relaxation delays and acquisition using the inverse gated decoupling scheme for suppression of the NOE. Additionally, the use of paramagnetic relaxation reagents (e.g.,  $\text{Co}(\text{acac})_2$ ) reduces the measurement times due to sizably shorter  $^{13}\text{C}$  spin-lattice relaxation times and considerable quench of the NOE. In cases of sensitivity problems the use of the highest possible magnetic field strength could be of general help.

## Fluorine-19

J C Lindon, Imperial College London, London, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Fluorine has a nuclear magnetic resonance (NMR)-active nucleus with one of the highest sensitivities, third only to proton ( $^1\text{H}$ ) and the radioactive tritium ( $^3\text{H}$ ). As it has favorable NMR properties, fluorine NMR has found widespread application in both chemistry and biology. This has resulted in a large number of reviews and books and there have been extensive compilations of solution-state  $^{19}\text{F}$  NMR chemical shifts and coupling constants in organic, organometallic, and inorganic compounds, these being very useful for confirmation of molecular structures. As well as studies on small molecules, a significant number of fluorinated polymers are important and  $^{19}\text{F}$  NMR spectroscopy can be used in their characterization, particularly the determination of polymer chain microstructure. In addition, the application of high-resolution techniques in solids, such as magic-angle spinning (MAS) and combined rotation and multiple pulse spectroscopy (CRAMPS), has expanded with a variety of applications in the literature. There are an increasing number of studies using  $^{19}\text{F}$  NMR spectroscopy in biology including the study of binding of fluorinated molecules to macromolecules, applications to membrane structure and flexibility, the elucidation of drug metabolites *in vitro*, and the study of the distribution and metabolism of compounds *in vivo*.

### Properties of the Nucleus

Fluorine possesses only one isotope,  $^{19}\text{F}$ , which has a spin  $I = 1/2$  and a sensitivity relative to  $^1\text{H}$  for an equal number of nuclei of 0.83. The magnetogyric ratio has a value of 0.94 that of  $^1\text{H}$ , so the basic resonance frequency for  $^{19}\text{F}$  is, for example, 282.2 MHz on a spectrometer that operates at a

field strength of 7.05 T with  $^1\text{H}$  NMR observation at 300 MHz.

### Sample Preparation and Spectrum Measurement

Samples for solution study are prepared in the usual manner as for  $^1\text{H}$  NMR spectroscopy. Degassing the solutions can be important because of the effect of paramagnetic oxygen on the  $^{19}\text{F}$  spin relaxation times. A number of substances have been proposed for chemical shift referencing, and for a time an external sample of trifluoroacetic acid was commonly used. Now, however, the standard reference compound is internal trichlorofluoromethane,  $\text{CFCl}_3$ , added at a few mole percent and with a fluorine chemical shift ( $\delta_{\text{F}}$ ) taken to be at 0.0 ppm. This compound is very volatile and quite unreactive, and therefore easy to remove from samples if necessary. At high-field strengths, the  $^{19}\text{F}$  NMR chemical shift is perturbed by the combined isotope effects of the various possible combinations of  $^{35}\text{Cl}$  and  $^{37}\text{Cl}$  containing molecules. This means that at best the signal is broadened and at worst an asymmetric multiplet structure from slightly different chemical shifts can be resolved. The current sign convention for fluorine chemical shifts is for negative values (denoted by  $\delta$  or ppm) to low frequency of  $\text{CFCl}_3$  (to the so-called high field) and increasing positive values to high frequency of  $\text{CFCl}_3$ . Early literature values of chemical shifts generally used the reverse sign convention and so care needs to be taken in relating recent data to older data. Some measurements have also used a number of secondary reference compounds and the conversion factors are given in Table 1.

The wide range of  $^{19}\text{F}$  NMR chemical shifts can lead to problems in data acquisition, in particular nonuniform excitation and poor digitization. For example, peaks from a typical organic compound sample containing  $\text{CFCl}_3$  and both aliphatic and aromatic fluorines can cover a spectral range of

## Fluorine-19

J C Lindon, Imperial College London, London, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Fluorine has a nuclear magnetic resonance (NMR)-active nucleus with one of the highest sensitivities, third only to proton ( $^1\text{H}$ ) and the radioactive tritium ( $^3\text{H}$ ). As it has favorable NMR properties, fluorine NMR has found widespread application in both chemistry and biology. This has resulted in a large number of reviews and books and there have been extensive compilations of solution-state  $^{19}\text{F}$  NMR chemical shifts and coupling constants in organic, organometallic, and inorganic compounds, these being very useful for confirmation of molecular structures. As well as studies on small molecules, a significant number of fluorinated polymers are important and  $^{19}\text{F}$  NMR spectroscopy can be used in their characterization, particularly the determination of polymer chain microstructure. In addition, the application of high-resolution techniques in solids, such as magic-angle spinning (MAS) and combined rotation and multiple pulse spectroscopy (CRAMPS), has expanded with a variety of applications in the literature. There are an increasing number of studies using  $^{19}\text{F}$  NMR spectroscopy in biology including the study of binding of fluorinated molecules to macromolecules, applications to membrane structure and flexibility, the elucidation of drug metabolites *in vitro*, and the study of the distribution and metabolism of compounds *in vivo*.

### Properties of the Nucleus

Fluorine possesses only one isotope,  $^{19}\text{F}$ , which has a spin  $I = 1/2$  and a sensitivity relative to  $^1\text{H}$  for an equal number of nuclei of 0.83. The magnetogyric ratio has a value of 0.94 that of  $^1\text{H}$ , so the basic resonance frequency for  $^{19}\text{F}$  is, for example, 282.2 MHz on a spectrometer that operates at a

field strength of 7.05 T with  $^1\text{H}$  NMR observation at 300 MHz.

### Sample Preparation and Spectrum Measurement

Samples for solution study are prepared in the usual manner as for  $^1\text{H}$  NMR spectroscopy. Degassing the solutions can be important because of the effect of paramagnetic oxygen on the  $^{19}\text{F}$  spin relaxation times. A number of substances have been proposed for chemical shift referencing, and for a time an external sample of trifluoroacetic acid was commonly used. Now, however, the standard reference compound is internal trichlorofluoromethane,  $\text{CFCl}_3$ , added at a few mole percent and with a fluorine chemical shift ( $\delta_{\text{F}}$ ) taken to be at 0.0 ppm. This compound is very volatile and quite unreactive, and therefore easy to remove from samples if necessary. At high-field strengths, the  $^{19}\text{F}$  NMR chemical shift is perturbed by the combined isotope effects of the various possible combinations of  $^{35}\text{Cl}$  and  $^{37}\text{Cl}$  containing molecules. This means that at best the signal is broadened and at worst an asymmetric multiplet structure from slightly different chemical shifts can be resolved. The current sign convention for fluorine chemical shifts is for negative values (denoted by  $\delta$  or ppm) to low frequency of  $\text{CFCl}_3$  (to the so-called high field) and increasing positive values to high frequency of  $\text{CFCl}_3$ . Early literature values of chemical shifts generally used the reverse sign convention and so care needs to be taken in relating recent data to older data. Some measurements have also used a number of secondary reference compounds and the conversion factors are given in Table 1.

The wide range of  $^{19}\text{F}$  NMR chemical shifts can lead to problems in data acquisition, in particular nonuniform excitation and poor digitization. For example, peaks from a typical organic compound sample containing  $\text{CFCl}_3$  and both aliphatic and aromatic fluorines can cover a spectral range of

250 ppm, which at a field strength of 11.7 T (i.e., 500 MHz for  $^1\text{H}$  NMR) corresponds to a spectral width of 117 500 Hz. To cover this frequency uniformly with a  $90^\circ$  pulse requires a pulse width of just over  $2\ \mu\text{s}$ , a value that solution-state commercial NMR spectrometers do not usually achieve. Fortunately, the need to do this can be avoided as measurements can often be focused on one region of the spectrum either by allowing signals to be aliased or by the use of digital filtering. The corresponding need for high digital resolution given the sharp  $^{19}\text{F}$  NMR lines and often highly resolved complex spin-coupled multiplets is also obvious and a 117 500 Hz spectral width with a digital resolution of only 0.5 Hz requires a Fourier transform size of 256 K words.

Particularly in organic molecules,  $^{19}\text{F}$  nuclei often show spin-spin coupling over many bonds to other nuclei. To simplify spectra when most of the couplings are between  $^{19}\text{F}$  and  $^1\text{H}$ , it is common to measure  $^1\text{H}$ -broadband-decoupled spectra. This can be quite difficult given the closeness of  $^{19}\text{F}$  and  $^1\text{H}$  NMR resonance frequencies and careful filtering of the fluorine observation channel is usually necessary.

Increasingly, two-dimensional (2D) NMR methods are playing a part in spectral assignment and in polyfluoro compounds  $^{19}\text{F}$ - $^{19}\text{F}$  COSY can be very useful for resonance assignment. Similarly,  $^1\text{H}$ - $^{19}\text{F}$  correlation spectra can be used to assign couplings between  $^1\text{H}$  and  $^{19}\text{F}$ . For polyfluoro compounds,

$^{13}\text{C}$ - $^{19}\text{F}$  correlation experiments can be useful but decoupling  $^{19}\text{F}$  from  $^{13}\text{C}$  over the full range of fluorine chemical shifts is generally only feasible using techniques such as globally optimized alternating-phase rectangular pulse decoupling. On the other hand, with the advent of inverse geometry probes and inverse detection pulse sequences, detection of  $^{13}\text{C}$ - $^{19}\text{F}$  correlations at the  $^{19}\text{F}$  NMR frequency will likely prove to be very useful especially in conjunction with the use of magnetic field gradients to eliminate fluorine signals from the  $^{12}\text{C}$  containing molecules that obscure the  $^{13}\text{C}$ -coupled  $^{19}\text{F}$  NMR signals.

## $^{19}\text{F}$ NMR Chemical Shifts

$^{19}\text{F}$  NMR chemical shifts cover a wide range, if organic and inorganic substances are considered. The extensive range of  $^{19}\text{F}$  NMR chemical shifts is exemplified by the series of fluorides shown in Table 2, ranging from  $-448$  ppm for ClF to  $+865$  ppm for  $\text{F}_2\text{O}_2$ .

For organic compounds, as is well known for  $^1\text{H}$  NMR chemical shifts,  $^{19}\text{F}$  NMR chemical shifts fall into diagnostic ranges with generally negative  $\delta_{\text{F}}$  values. Major compilations of chemical shifts exist in the reviews given in the Further Reading section, most concentrating on organic compounds. To illustrate the wide range of  $^{19}\text{F}$  NMR chemical shifts in an organic compound, Figure 1 demonstrates the range ( $>100$  ppm) observed for such a relatively simple molecule. This shows the 564 MHz  $^{19}\text{F}$  NMR spectrum of 6H-perfluorohex-1-ene (1) in solution in  $\text{CDCl}_3$ .

**Table 1**  $^{19}\text{F}$  chemical shifts of reference compounds, relative to  $\text{CFCl}_3$  at  $\delta_{\text{F}} = 0.0$  ppm

Compound	$\delta_{\text{F}}$ (ppm)	Compound	$\delta_{\text{F}}$ (ppm)
$\text{CF}_3\text{COOH}$	$-78.5$	<i>Cyclo</i> - $\text{C}_4\text{F}_8$	$-136.0$

**Figure 1** 564 MHz  $^{19}\text{F}$  NMR spectrum of 6H-perfluorohex-1-ene (1) in  $\text{CDCl}_3$  solution. Chemical shifts are quoted relative to  $\text{CFCl}_3$  and assignments are as shown.

Assignment of the chemical shifts can be made based on diagnostic coupling constants and the use of 2D homonuclear correlation spectroscopy (COSY) and these are also indicated in **Figure 1**. The chemical shifts, in ppm from  $\text{CFCl}_3$ , are  $-90.02$  (F1),  $-106.70$  (F1'),  $-190.71$  (F2),  $-119.69$  (F3),  $-131.38$  (F4),  $-126.78$  (F5), and  $-138.95$  (F6). It is notable that  $-\text{CF}_2-$  and  $=\text{CF}$  resonances cover similar chemical shift ranges, unlike the  $^1\text{H}$  NMR chemical shifts of corresponding  $-\text{CH}_2-$  and  $=\text{CH}$  groups.

Much effort has been given to evaluating substituent effects on fluorine chemical shifts especially in fluoroaromatic molecules. Additionally, because of the high sensitivity of fluorine NMR, it has been used extensively to study bonding in, and reactions of, a wide range of inorganic and organometallic species and the reader is referred to the Further Reading section for details of individual studies.

#### Solvent and Temperature Dependence of $^{19}\text{F}$ NMR Chemical Shifts

Significant solvent effects, in particular the effect of solvent dielectric constant, are known to occur for  $^{19}\text{F}$  NMR chemical shifts and this has led to significant differences between literature values for a given species and also has been the subject of considerable theoretical effort.

$^{19}\text{F}$  NMR chemical shifts are also very sensitive to temperature. Although their temperature dependence has been used extensively to evaluate free energies of activation for conversion of rotamers and ring conformers in substituted ethanes and other

conformationally mobile species, it is necessary to realize that these chemical shifts can be intrinsically temperature dependent, including the resonance of any internal reference compound.

#### Anisotropy of $^{19}\text{F}$ NMR Chemical Shifts

Although only the trace of the chemical shift tensor is measured in isotropic solution, in general  $^{19}\text{F}$  nuclei have large chemical shift anisotropies and in anisotropic media such as solids or liquid crystal solutions, which can include biological matrices such as membranes, the spectrum can be severely dependent on such parameters in that the observed chemical shift is dependent on the orientation of the molecule relative to the magnetic field. The definition of the chemical shift anisotropy in terms of molecule-based axes depends on the symmetry of the molecule under study but it can easily have a magnitude of tens or hundreds of ppm, for example, being 158 ppm in hexafluorobenzene, which has an isotropic shift of  $-163$  ppm.

#### Spin Coupling to Fluorine

##### Solvent and Temperature Dependence

Spin-spin couplings involving  $^{19}\text{F}$  can also be rather solvent dependent. For example, in simple substituted fluoroethenes, the  $^3J_{\text{HF}}$  in fluoroethene itself has values of 19.6 Hz for the *cis* coupling and 51.8 Hz for the *trans* coupling in cyclohexane solution, and these vary over a range of 2.1 and 4.6 Hz, respectively, in

different solvents. Similarly, the  $^2J_{\text{FF}}$  in 1,1-difluoroethene has a value of 30.7 Hz in cyclohexane but can vary by up to 8.8 Hz in other solvents. Coupling constants can be temperature dependent because of various aspects of molecular conformational changes, but apart from this, couplings to fluorine can have marked intrinsic temperature dependence. For example, the  $^2J_{\text{FF}}$  in 1,1-difluoroethene has a temperature coefficient of  $1.39 \text{ Hz K}^{-1}$  in hexane but only  $0.16 \text{ Hz K}^{-1}$  in dimethylformamide. Thus, care must be taken in relating changes in coupling constants to changes in molecular conformations.

### Anisotropy of Coupling Constants

In principle, NMR spectroscopy in liquid crystal solutions, or in other situations where the molecule can be oriented, allows the measurement of elements of the spin-coupling tensor other than the simple isotropic trace. Unfortunately, this anisotropy enters the NMR Hamiltonian in exactly the same fashion as the corresponding dipolar couplings that are also observed in anisotropic media and hence cannot be measured separately. Thus, estimation of this anisotropy relies on any deviation between the observed dipolar coupling and that calculated from geometrical considerations. In principle, the coupling tensor can also be asymmetric.

### $^1\text{H}$ – $^{19}\text{F}$ Spin Coupling

Couplings between  $^1\text{H}$  and  $^{19}\text{F}$  nuclei are, in general, very dependent on substitution and on electronegativity. For example, for  $^2J_{\text{HF}}$  in methanes,  $\text{CHFXY}$ , it is possible to predict the coupling to  $\sim 2 \text{ Hz}$  using the relationship:

$$^2J_{\text{HF}} = 78.76 + 8.45E_{\text{X}}E_{\text{Y}} - 16.73(E_{\text{X}} + E_{\text{Y}}) \quad [1]$$

where  $E_{\text{X}}$  and  $E_{\text{Y}}$  are the electronegativities of the substituents. A typical value where X and Y are both carbon would be  $\sim 50 \text{ Hz}$ . Vicinal  $^1\text{H}$ – $^{19}\text{F}$  spin coupling in aliphatic systems is dependent on the dihedral angle between the CH and CF bonds in a Karplus-type relationship, which has been the subject of much theoretical prediction. Long-range  $^1\text{H}$ – $^{19}\text{F}$  coupling is often observed, values being usually larger than the corresponding  $^1\text{H}$ – $^1\text{H}$  coupling.

### $^{13}\text{C}$ – $^{19}\text{F}$ Spin Coupling

Carbon–fluorine coupling also shows large variations with substituents, including the one-bond coupling that has a range centered  $\sim 300 \text{ Hz}$ . Two-bond couplings are much smaller and have values up to  $\sim 10 \text{ Hz}$ . Long-range coupling is often observed in fluoroaromatic compounds but the effect of

substitution is difficult to ascertain because very few relative signs of couplings have been measured, although it is probable that  $^1J_{\text{CF}}$  is always negative and  $^2J_{\text{CF}}$  and  $^3J_{\text{CF}}$  are positive.

### $^{19}\text{F}$ – $^{19}\text{F}$ Spin Coupling

The data on coupling between  $^{19}\text{F}$  nuclei are very widespread and these can exist over many intervening bonds. Again extensive compilations of data are presented in the Further Reading section. Two-bond couplings vary widely according to geometry and structure; for instance, being 27 Hz in 1,1-difluoroethene and 87 Hz in trifluoroethene, and over 200 Hz in fluorinated cyclobutanes. Three-bond  $^{19}\text{F}$ – $^{19}\text{F}$  spin coupling shows good consistency in aromatic systems allowing structural diagnosis, but in aliphatic systems large variations can occur making its use as a structural and conformational tool questionable because substituent effects can compete with any dihedral angle effects. Four-bond couplings are sometimes larger than three-bond couplings and particularly in cyclohexanes are diagnostic in that the coupling between pairs of axial  $^{19}\text{F}$  nuclei is  $\sim 26 \text{ Hz}$ , that between pairs of equatorial  $^{19}\text{F}$  nuclei is  $\sim -6$  to  $-9 \text{ Hz}$  and the axial–equatorial coupling is near zero. The axial–axial situation has the two carbon–fluorine bonds eclipsed and, in other situations like this a large positive  $^4J_{\text{FF}}$  can be measured, such as 1,8-difluoronaphthalene where the coupling is 58.8 Hz. These large couplings have been used to postulate a ‘through-space’ mechanism of coupling as opposed to the usual recognized mechanism of through-bond coupling. Indeed, when two  $^{19}\text{F}$  nuclei are close in space but separated by many bonds, large couplings can result, for example, in (2) the  $J_{\text{FF}}$  is 43.2 Hz, whilst in (3)  $J_{\text{FF}}$  has the large value of 174 Hz.

$^{19}\text{F}$ – $^{19}\text{F}$  spin coupling in aromatic systems is useful in determining substitution patterns and structure in that  $^3J_{\text{FF}}$  is remarkably insensitive to substitution being close to  $-20 \text{ Hz}$  whilst  $^4J_{\text{FF}}$  and  $^5J_{\text{FF}}$  are very dependent on substituents. For  $^5J_{\text{FF}}$  only one substituent parameter is necessary while for  $^4J_{\text{FF}}$  three parameters are needed. The coupling constants are calculated using the equations below (where *o*, *m*, and *p* correspond to *ortho*, *meta*, and *para*,

respectively) and the parameters in Table 3 are used:

$${}^4J_{\text{FF}} = 5.8 + {}^4X(o-o) + \Sigma {}^4X(o-p) + {}^4X(m-m) \quad [2]$$

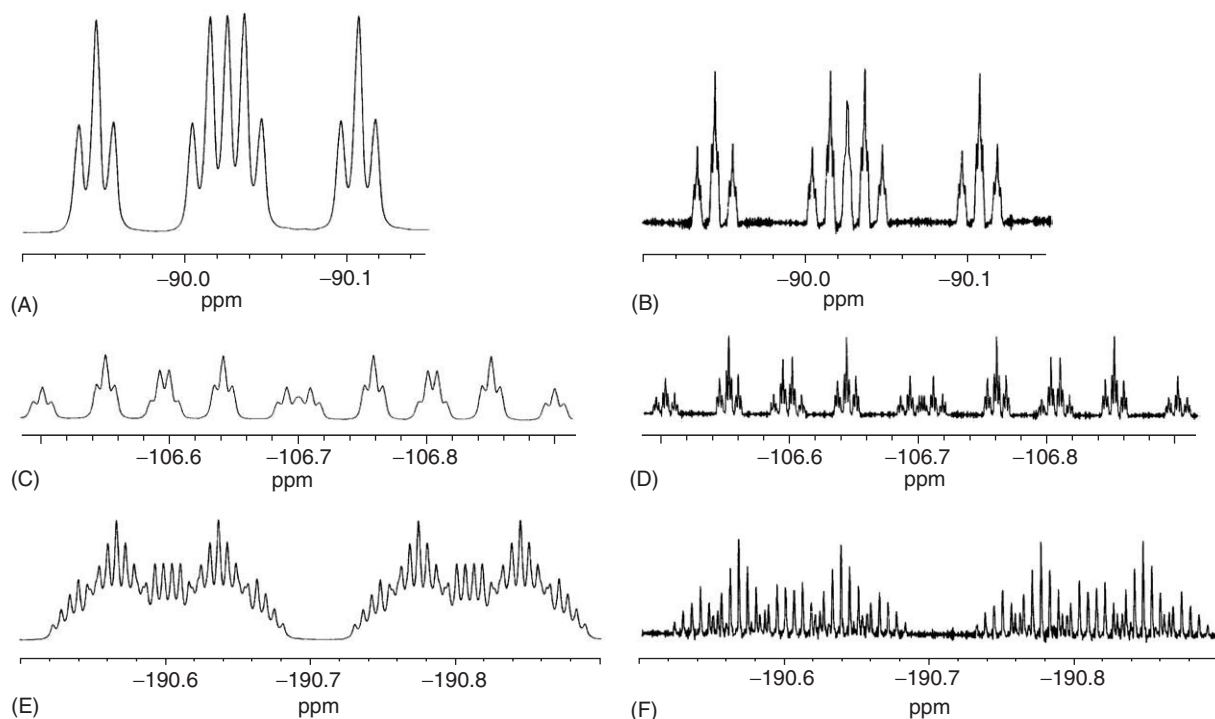

$${}^5J_{\text{FF}} = 18.1 + \Sigma {}^5X \quad [3]$$

As an example of the complexity of the  ${}^{19}\text{F}$  NMR spectra of polyfluorocompounds, Figure 2 shows expansions of the individual resonances of the olefinic fluorines from the spectrum of 6H-perfluorohex-1-ene (1)

**Table 3** Substituent parameters for *meta* and *para*  ${}^{19}\text{F}$ – ${}^{19}\text{F}$  spin coupling

Substituent	${}^4X$			${}^5X$
	Ortho-ortho	Ortho-para	Meta-meta

given in Figure 1. On the left is given the result obtained by Fourier transformation of the raw data and on the right is shown the result of resolution enhancement of the acquired data using the Lorentzian–Gaussian transformation method. The complexity of each of the bands indicates a wealth of spin–spin coupling over two to six bonds. The signal arising from F1 shows two doublet splittings corresponding to the two-bond geminal interaction of 52 Hz and a three-bond *cis* interaction of 40 Hz, together with a series of triplet splittings caused by coupling to the  $-\text{CF}_2\text{CF}_2\text{CF}_2-$  fragment over four, five, and six bonds. The band due to F1' also exhibits many couplings and the major splittings comprise doublets of 118 Hz (the three-bond *trans* coupling, which is known to be of opposite sign to the geminal and *cis* couplings between olefinic fluorines) and 52 Hz (the two-bond geminal coupling seen on the F1 resonance). In addition, there are three sets of triplets arising from coupling to the  $-\text{CF}_2\text{CF}_2\text{CF}_2-$  fragment, with the four-bond coupling being  $\sim 28$  Hz. The resonance arising from F2 is also complex showing the *trans* and *cis* couplings as doublets together with triplets from coupling to the  $-\text{CF}_2\text{CF}_2\text{CF}_2-$  fragment (four- to six-bond couplings). The exact assignment of these smaller couplings could be achieved using selective spin-decoupling experiments.

**Figure 2** Expansions of the individual resonances of the olefinic fluorines in the 564 MHz  ${}^{19}\text{F}$  NMR spectrum of 6H-perfluorohex-1-ene (1) in  $\text{CDCl}_3$  solution. On the left is shown the result of Fourier transformation of the raw data and on the right is given the result of resolution enhancement. Assignments are F1 (top), F1' (center), and F2 (bottom).

### **$^{19}\text{F}$ Spin Coupling to Other Nuclei**

The coupling between  $^{19}\text{F}$  and some heteronuclei can be very large and diagnostic of bonding situations. To give some examples of the wide range of values, the coupling to tungsten in alkoxy tungsten fluorides is  $\sim 60\text{--}70\text{ Hz}$ . In platinum complexes, the coupling between platinum and directly bonded  $-\text{CF}_3$  groups (i.e., over two bonds) can be as large as  $750\text{ Hz}$ . The one-bond coupling between phosphorus and fluorine in trifluorophosphoranes, for example,  $\text{MeS}(\text{Me})\text{PF}_3$ , and tetrafluorophosphoranes can be as large as  $1000\text{ Hz}$  whilst difluorophosphoranes generally have values between  $600$  and  $800\text{ Hz}$ . Some directly bonded phosphorus–fluorine coupling constants can be even bigger going as high as  $1284\text{ Hz}$  in  $\text{EtOPF}_2$ .  $^{29}\text{Si}$ – $^{19}\text{F}$  directly bonded coupling constants are more modest being  $\sim 200\text{--}300\text{ Hz}$  in fluorosilanes.

### **$^{19}\text{F}$ NMR Relaxation Times**

Few studies of  $^{19}\text{F}$  NMR relaxation times have been reported considering the high sensitivity of the nucleus, and this is probably due to the extensive spin coupling observed in fluorine NMR leading to extensive cross-relaxation effects and difficulty in interpreting the results. Whilst the relaxation times of  $^1\text{H}$  nuclei are usually dominated by dipole–dipole terms, and this is often also true for  $^{13}\text{C}$  relaxation in  $\text{CH}$ ,  $\text{CH}_2$ , and  $\text{CH}_3$  groups, it is quite feasible for the chemical shift anisotropy term to be a major factor in relaxation in the case of  $^{19}\text{F}$ . This term is very field dependent, the relaxation rate scaling as the square of the field strength. Some use has been made of  $^{19}\text{F}$  relaxation times ( $T_1$ ,  $T_2$ , and  $T_{1\rho}$ ) in determining dynamics in a co-polymer of tetrafluoroethene and hexafluoropropene. The chemical shift anisotropy contribution to  $^{19}\text{F}$  NMR relaxation can be a disadvantage because it can cause a field-dependent broadening, and hence loss of resolution in studies of binding between small molecules and proteins, but it can also be used to advantage in some circumstances to extract values of the chemical shift anisotropy that can be used in situations of partial ordering in order to obtain information on the averaging process.

## **Analytical Applications of $^{19}\text{F}$ NMR**

### **Chemicals and Polymers**

Because fluorine possesses a spin- $1/2$  nucleus with high NMR sensitivity, analytical applications of fluorine NMR to small molecules follow closely those using  $^1\text{H}$  NMR spectroscopy. Recently, the use of

high throughput screening for biological activity of small molecules in pharmaceutical research has entailed the use of new approaches and  $^{19}\text{F}$  NMR spectroscopy has been used for detection of target-ligand binding.

The parallel with  $^1\text{H}$  NMR spectroscopy also applies to studies in the solution state of macromolecules such as polymers where fluorinated species are commercially important.

However, the difficulty of studying polymers in solution and the need to understand their solid-state properties has led to developments in solid-state NMR. To obtain high-resolution  $^{19}\text{F}$  NMR spectra of solids it is necessary to use MAS to remove the chemical shift anisotropic contribution to the line-widths, and as this alone is not sufficient to remove  $^1\text{H}$ – $^{19}\text{F}$  heteronuclear and  $^{19}\text{F}$ – $^{19}\text{F}$  homonuclear dipolar couplings, it has to be combined with other methods. Such pulse sequences exist and have been used to sharpen solid-state  $^{19}\text{F}$  NMR spectra for a number of fluorine-containing polymers. If the polymer has flexibility, then MAS alone may be sufficient and this approach has been successfully applied in fluoro-polymers of the type  $-\text{CF}_2-\text{O}-\text{CF}_2-\text{O}-\text{CF}_2-\text{CF}_2-\text{O}-$  in order to analyze for polymer sequence information and end-group effects. Similar methods have been used on dental materials such as fluoro-apatite and its derivatives in order to investigate the various fluorine environments. If it is necessary to study rigid solid materials with  $^{19}\text{F}$ – $^{19}\text{F}$  dipolar coupling, there is a requirement for very fast spinning if multiple pulse line narrowing techniques are not used and speeds in excess of  $20\text{ kHz}$  have been used on highly fluorinated co-polymers. The use of additional line narrowing methods based on multiple pulse sequences when combined with MAS is termed CRAMPS and has been applied to simple fluoro-organic molecules in order to measure shielding tensors and molecular mobility in the solid state. In addition, studies on polymers have probed solid-state morphology and molecular orientation. These techniques cannot be regarded as routine in the same way that solution-state NMR has become, but the information obtainable is difficult to acquire by other means and makes the effort worthwhile.

A number of studies have introduced fluorine atoms into amino acids and then used these to obtain fluorine-labeled proteins.  $^{19}\text{F}$  NMR spectroscopy of such proteins can then be carried out in conjunction with other multidimensional NMR experiments to obtain their 3D structures. The fluorine label can also be used as a probe to study molecular dynamics, protein structural changes caused by the introduction of the label and intermolecular interactions.

### Drug Metabolism and Cellular Applications

The use of indicator molecules containing fluorine that can be transported into cells has proved useful for monitoring intracellular environments. The  $^{19}\text{F}$  NMR shifts of various specifically designed complexant molecules are strongly dependent on pH,  $\text{Na}^+$ , or  $\text{Ca}^{2+}$  and provide a sensitive method of monitoring intracellular  $\text{Na}^+$  or  $\text{Ca}^{2+}$  levels or pH and pH gradients, and to distinguish intracellular pH from extracellular pH because of the different chemical shifts.  $^{19}\text{F}$  NMR spectroscopy has also been used to follow the metabolism and distribution of 2-fluoro-2-deoxyglucose and 3-fluoro-3-deoxyglucose used for the investigation of brain and cardiac glucose metabolism and the employment of fluorinated polyamines has been used with  $^{19}\text{F}$  NMR spectroscopy for detecting hypoxic cells in tumors.

A considerable proportion of drugs under development contain one or more fluorine atoms that act as useful tracer nuclei for NMR studies of drug metabolism when measuring NMR spectra of cell extracts or biological fluids.  $^{19}\text{F}$  NMR spectroscopy is particularly useful because of the high sensitivity of the  $^{19}\text{F}$  nucleus, its wide chemical shift range that allows resolvable chemical shifts for metabolic or chemical changes up to  $\sim 10$  bonds away from the fluorine, and, because of the negligible background from other fluorine-containing species in the environment, there are few if any interfering resonances. Also, there are no dynamic range problems for the NMR acquisition. For example, for flucloxacillin it has been shown that the parent molecule (4) and its metabolites can be detected and quantified in rat urine using a combination of 1D and 2D NMR methods. The presence of the parent drug and the major metabolite, the 5'-hydroxymethyl derivative, was confirmed by the study, and the detection of two previously unidentified metabolites, the C-5 isomers (*R* and *S*) of flucloxacillin penicilloic acid were demonstrated.

(4)

Much effort has been expended in studying the metabolism of fluorinated pyrimidines because the fluorine in the pyrimidine ring is rarely lost during metabolism and also because of the importance of this class of compounds as anticancer drugs. These

compounds, in particular 5-fluorouracil (FU), are metabolized to produce a variety of products. The number of studies published reflects the importance of this drug in the clinic and the effectiveness of  $^{19}\text{F}$  NMR spectroscopy. Thus, studies have ranged from those on body fluids such as plasma and urine, through tissue extracts to full *in vivo* investigations. FU remains an important therapy mainly for colon and breast cancers and the metabolism of FU is shown in Figure 3. Two types of process are possible, namely catabolic metabolism or anabolic processes that ultimately lead to incorporation of fluorinated species into nucleic acids. The balance between anabolism and catabolism may be different in different tissues and subjects and may be a significant factor in therapeutic benefit versus toxic side-effects. The cytotoxicity results from the anabolic route because of the inhibition by 5-fluoro-2'-deoxyuridine-5'-monophosphate of thymidylate synthetase and hence DNA synthesis and by incorporation of 5-fluorouracil components into RNA and DNA.  $^{19}\text{F}$  NMR spectra from plasma from patients on FU infusion therapy showed the resonances from FU itself and peaks from three expected metabolites (dihydro-FU, 2-fluoro-3-ureidopropionic acid, and 2-fluoro-3-aminopropionate) and in some cases fluoride ion was also detected. Detailed pharmacokinetics was also possible. In urine, a similar picture emerges with over 97% of the observed  $^{19}\text{F}$  NMR spectral intensity due to the same species, although *N*-carboxy-2-fluoro-3-aminopropionate and two other unidentified species were observed. Human biliary excretion has also been studied and led to the characterization of 2-fluoro-3-aminopropionate complexed with bile acids. FU metabolism has also been studied in *Escherichia coli* bacteria, murine, and human tumor cells, excised tissue samples from patients receiving FU therapy where it was shown that uptake and anabolic metabolism of FU was lower in liver metastases compared to normal liver. Finally, *in vivo* studies have been conducted using both rodents and humans, and in particular in the clinical situation, surface coil NMR spectroscopy has been used to study the catabolism of FU to 2-fluoro-3-aminopropionate in the liver with a time resolution of 9 min.

### Membranes and Macromolecule Binding Studies

$^{19}\text{F}$  NMR spectroscopy can be used to study membrane structure and dynamics by replacing hydrogens on a phospholipid molecule by fluorines. Because of the favorable NMR properties of fluorine, it is an ideal probe nucleus as an adjunct to using  $^{13}\text{C}$  or  $^2\text{H}$  incorporation for this application. In fact, it is preferable to replace a  $\text{CH}_2$  group by a  $\text{CF}_2$  group rather

**Figure 3** The fluorinated derivatives of 5-fluorouracil involved in (A) catabolic and (B) anabolic metabolism.

than a CHF group because it is then often possible to observe  $^{19}\text{F}$ – $^{19}\text{F}$  dipolar coupling and also no additional chirality is incorporated. Application have included sonicated model membranes, oriented synthetic bilayers, liposomes that give powder-type spectra, and biosynthetically derived bacterial membranes grown using media containing fluorinated fatty acids. It is possible to use the derived NMR parameters to yield information on order parameters along the hydrocarbon chains, to investigate the phase diagram for the heterogeneous systems, and to study the effect of added cholesterol or proteins, for example, on the bilayer dynamics and order. In oriented systems it is possible to use the  $^{19}\text{F}$  chemical shift anisotropy to advantage to yield ordering information and it can also be feasible to measure the  $^{19}\text{F}$ – $^{19}\text{F}$  dipolar coupling, which leads directly to the degree of order along the inter-fluorine axis. It has been possible to synthesize fluorinated fatty acids where the fluorine probes are placed at different parts of the aliphatic chains and incorporate these into membranes. It has to be recognized that these

fluorinated probe molecules are not natural phospholipid components and the question has to be asked how great a perturbation they introduce. The C–F bond is  $\sim 0.02$ – $0.03$  nm longer than a C–H bond and as well as any electronic effects of the substitution there have to be steric consequences. For example, relative to dimyristoylglycerophosphorylcholine, the compounds which have 4,4- $\text{F}_2$ , 8,8- $\text{F}_2$ , and 12,12- $\text{F}_2$  substituents have different liquid crystal to isotropic transition temperatures by +5.0, –7.4, and –3.8 K, respectively.

Fluorine-containing ligands have proved popular for probing the binding of small molecules to proteins. There are the usual advantages of using  $^{19}\text{F}$  NMR spectroscopy but also the disadvantages of the potential steric and electronic changes to the local binding structure by introducing the fluorine substitution and the difficulty of interpreting the  $^{19}\text{F}$  NMR relaxation times because of the significant chemical shift anisotropy contribution. The effect of this on  $T_2$  means a rapidly increasing linewidth at higher magnetic field strengths. Studies have been carried

out on ligands that are in exchange with a binding site on the protein (fast, slow, or intermediate on the NMR timescale) or ligands that are covalently bonded or introduced into the structure of the protein, for example, as fluorinated amino acids. The parameters that can be measured and are influenced by binding are chemical shifts, integrals,  $T_1$ ,  $T_2$ , NOEs, molecular diffusion coefficients measured by special NMR pulse sequences, and possibly spin coupling constants, if the linewidths are narrow enough to resolve them. In addition, exchange rates can be calculated based on full lineshape analysis, transfer of saturation experiments or the Carr–Purcell–Meiboom–Gill spin-echo sequence. There is the usual difficulty of interpreting results quantitatively if there is more than one binding site and if weak nonspecific binding also takes place. Through the use of  $^{19}\text{F}$ – $^1\text{H}$  NOE experiments it is possible to provide evidence of the conformation of the bound molecule and by using a 2D NOE sequence with a short enough mixing time and following the intensity of NMR cross-peaks, spin diffusion effects can be minimized.

It has been observed that models for dynamics of a ligand at a binding site which can explain  $T_1$  and  $^{19}\text{F}$ – $^1\text{H}$  NOE data often underestimate the linewidths or  $T_2$ . This additional line-broadening is thought to arise because the ligand can exchange between several conformational states in the ligand–protein structure and the  $^{19}\text{F}$  label can experience several different chemical shifts that are not averaged by the exchange.

The  $^{19}\text{F}$  NMR chemical shift changes induced by protein binding are usually to high frequency by up to 9 ppm although larger shifts and shifts to low frequency are known. This shift can occur as a result of electrostatic effects, van der Waals interactions, dipolar-induced electric fields, or magnetic anisotropy effects caused by adjacent carbonyl groups or aromatic rings. The shifts are temperature dependent and any deviation from a linear high-frequency shift or a shift greater than  $0.01\text{ ppm K}^{-1}$  can indicate a protein conformational change or the onset of an exchange process. If the solvent is changed from  $\text{H}_2\text{O}$  to  $\text{D}_2\text{O}$ , a fluorine probe nucleus can experience an isotope shift, typically  $0.2$ – $0.3\text{ ppm}$  to low frequency. This effect can be used to probe whether the protein-bound ligand is exposed to solvent or solvent-accessible exchangeable protons.

The consequences of introducing the fluorine probe have to be considered. Replacement of a C–H by a C–F makes the ligand more hydrophobic and hence this can affect binding properties. Evidence so far accumulated indicates that fluorine substitution does not, in general, have a significant influence on the tertiary structure of proteins.

### ***In Vivo* $^{19}\text{F}$ NMR Spectroscopy**

Localized *in vivo*  $^{19}\text{F}$  NMR spectroscopy has been used to monitor the distribution of drugs. Unlike  $^1\text{H}$  NMR spectroscopy, there is no need to suppress the large water resonance, and the relatively high sensitivity of fluorine NMR makes this an attractive approach. The advantage of spectroscopy is that it yields both spatial and chemical information at the same time. For example, the methods have been applied to the neuroleptic drug trifluoroperazine in the rat brain and extensive studies have concentrated on the uptake and elimination of fluorinated anesthetics because of the relatively high concentrations that can be achieved *in vivo*. Detailed pharmacokinetic studies have also been undertaken using  $^{19}\text{F}$  NMR *in vivo*, especially for 5-FU.

The anesthetic compound halothane,  $\text{CF}_3\text{CHBrCl}$ , is metabolized in the liver and this process has been monitored using  $^{19}\text{F}$  NMR spectroscopy, both *in vivo* and in dissected rat livers. Initially, several resonances were observed *in vitro* which did not correspond to trifluoroacetate or fluoride, two known metabolic products. Using surface coil NMR experiments *in vivo*, it has been possible to show that the halothane has a first-order decay in the liver with a half-life of 2.5 h, that trifluoroacetate was observed 8 h after dosing, and that induction of liver enzymes shortened this period considerably. No other resonances were observed *in vivo* but in liver extracts other molecules were also detected, namely, fluoride,  $\text{CF}_3\text{CH}_2\text{Cl}$ , and  $\text{CHF}_2\text{CH}_2\text{Cl}$ .

The  $^{19}\text{F}$  relaxation times of the fluorine nuclei in perfluorocarbons have been shown to be linearly inversely dependent on oxygen concentration due to the paramagnetic effect of oxygen. This has been shown to be of potential use for monitoring the level of  $p\text{O}_2$  in tissues and organs.

### **$^{19}\text{F}$ Magnetic Resonance Imaging**

The potential of using the fluorine resonances of perfluoro-aliphatic compounds to carry out NMR imaging has been explored. One material, a mixture of perfluorodecalin and perfluorotripropylamine, was developed as a blood substitute and has been undergoing clinical trials as a radiotherapy potentiators. Using these molecules, the time-course of the distribution and retention of the compounds in tumor-bearing mice has been explored and the results correlated with  $^1\text{H}$  magnetic resonance imaging (MRI) results. The  $^{19}\text{F}$  MRI measurements demonstrated the preferential location of the substances in the spleen and liver and a combination of imaging and *in vivo* spectroscopy showed that although the compounds left the blood stream within hours, they were retained in tissues at later times and the

compounds accumulated in tumors in a dose-dependent fashion, at levels 10–100 times lower than those in the spleen or liver. Other studies include one that followed the gastrointestinal transport in the rat of a nondisintegrating pellet containing a fluorinated drug derivative. Also, the detailed distribution of a fluorinated drug has been attempted in that  $^{19}\text{F}$  NMR images have been obtained showing the distribution of an antifolate anticancer agent in the mouse. This compound, an inhibitor of thymidylate synthetase, was administered intravenously and images obtained with a time resolution of 4 and 20 min, respectively, for 2D and 3D imaging. The images showed high concentrations of the drug in the gall bladder, urinary bladder, and small intestine. The methods will probably be limited by the acceptable concentrations of the drugs that can be achieved in the body but with technology and methods continuing to develop, the field promises to become very useful.

## Introduction

Nitrogen is a very important element in organic, inorganic, and organometallic chemistry as well as in biochemistry. It combines with practically all elements of the periodic table. Nitrogen has oxidation numbers from  $-3$  to  $5$ , coordination numbers from  $1$  to  $6$ , and bond order from  $1$  to  $3$ . All these properties can be studied by means of nitrogen NMR spectroscopy.

There are two naturally occurring isotopes of nitrogen,  $^{14}\text{N}$  and  $^{15}\text{N}$ . The  $^{14}\text{N}$  isotope has almost

100% natural abundance (Table 1) and its theoretical relative sensitivity is much higher than that of  $^{15}\text{N}$ . However,  $^{14}\text{N}$  NMR spectroscopy suffers from the fact that  $^{14}\text{N}$  is a quadrupolar nucleus ( $I = 1$ ). Despite the relatively small quadrupole moment ( $Q = 0.0017 \times 10^{-28} \text{ m}^2$ ),  $^{14}\text{N}$  NMR signals are commonly broad ( $w_{1/2}$  are tens to thousands of Hz) except for highly symmetrical environments (e.g.,  $\text{NR}_4^+$ ,  $\text{NO}_3^-$ , etc.) and some special cases (e.g., isocyanates R-NC) in which the signals are reasonably narrow.

In  $^{15}\text{N}$  NMR spectra, the line widths are comparable to those for  $^1\text{H}$  and  $^{13}\text{C}$ . Thus, in spite of very low sensitivity, low natural abundance, negative magnetogyric ratio, and the often long relaxation times of the  $^{15}\text{N}$  nucleus (Table 1),  $^{15}\text{N}$  spectroscopy has been the technique of choice.

## Introduction

Nitrogen is a very important element in organic, inorganic, and organometallic chemistry as well as in biochemistry. It combines with practically all elements of the periodic table. Nitrogen has oxidation numbers from  $-3$  to  $5$ , coordination numbers from  $1$  to  $6$ , and bond order from  $1$  to  $3$ . All these properties can be studied by means of nitrogen NMR spectroscopy.

There are two naturally occurring isotopes of nitrogen,  $^{14}\text{N}$  and  $^{15}\text{N}$ . The  $^{14}\text{N}$  isotope has almost

100% natural abundance (Table 1) and its theoretical relative sensitivity is much higher than that of  $^{15}\text{N}$ . However,  $^{14}\text{N}$  NMR spectroscopy suffers from the fact that  $^{14}\text{N}$  is a quadrupolar nucleus ( $I = 1$ ). Despite the relatively small quadrupole moment ( $Q = 0.0017 \times 10^{-28} \text{ m}^2$ ),  $^{14}\text{N}$  NMR signals are commonly broad ( $w_{1/2}$  are tens to thousands of Hz) except for highly symmetrical environments (e.g.,  $\text{NR}_4^+$ ,  $\text{NO}_3^-$ , etc.) and some special cases (e.g., isocyanates R-NC) in which the signals are reasonably narrow.

In  $^{15}\text{N}$  NMR spectra, the line widths are comparable to those for  $^1\text{H}$  and  $^{13}\text{C}$ . Thus, in spite of very low sensitivity, low natural abundance, negative magnetogyric ratio, and the often long relaxation times of the  $^{15}\text{N}$  nucleus (Table 1),  $^{15}\text{N}$  spectroscopy has been the technique of choice.

**Table 1** Basic properties important from the viewpoint of NMR spectroscopy of selected nuclei

Isotope	Natural abundance (%)	Spin number <i>I</i>	Magnetogyric ratio ( $\gamma/10^7$ ) <sup>a</sup>	RS <sup>b</sup>	RF <sup>c</sup> (MHz)
<sup>1</sup> H	99.99	1/2	26.751	5680	500.0

<sup>14</sup> N	99.635	1	1.932	5.69	36.1
<sup>15</sup> N	0.365	1/2	−2.711	0.022	50.6

<sup>a</sup>Magnetogyric ratio  $\gamma$  (rad T<sup>−1</sup> s<sup>−1</sup>).<sup>b</sup>RS, relative sensitivity at natural isotopic abundance level to <sup>13</sup>C.<sup>c</sup>RF, resonance frequency in MHz at a field of 11.7 T.

## Instrumental and Experimental Requirements for <sup>15</sup>N NMR

Nitrogen-15 NMR spectra are obtained almost exclusively by the pulsed Fourier transform technique. An NMR spectrometer must be equipped with either a single <sup>15</sup>N probe or a multinuclear tuneable probe and appropriate frequency synthesizer and detector. Instruments with magnetic field strengths as high as possible and wide NMR tube diameters are recommended for direct NMR measurements because of the low sensitivity of <sup>15</sup>N NMR measurements. Small and negative magnetogyric ratios can lead to strong enhancements of signals corresponding to proton-bearing nitrogens due to the nuclear Overhauser effect (NOE). A theoretical NOE of −4.93 is obtained (see equation below) for the case where the mechanism of spin–lattice relaxation *T*<sub>1</sub> is solely dipole–dipole:

$$\text{NOE} = 0.5 \frac{\gamma_{\text{H}} T_1}{\gamma_{\text{N}} T_1^{\text{DD}}} \quad [1]$$

where  $\gamma_{\text{H}}$  and  $\gamma_{\text{N}}$  are the magnetogyric ratios of hydrogen and nitrogen-15, respectively, and *T*<sub>1</sub><sup>DD</sup> is the dipole–dipole relaxation time. Partial dipolar relaxation for tertiary nitrogens may result in null signals (NOE = −1), as follows from the equation:

$$\frac{M_z}{M_z^0} = 1 + 0.5 \frac{\gamma_{\text{H}} T_1}{\gamma_{\text{N}} T_1^{\text{DD}}} \quad [2]$$

where *M*<sub>z</sub> is the *z*-magnetization and *M*<sub>z</sub><sup>0</sup> is the *z*-magnetization at thermal equilibrium. In the latter case, an application of gated proton decoupling (decoupler ‘on’ during acquisition) is recommended. Chromium(III) acetylacetonate is often used as the so-called relaxation reagent to shorten relaxation times and suppress the dipole–dipole relaxation mechanism. Obtaining signals of all nitrogen atoms (differing considerably in relaxation mechanisms) in <sup>15</sup>N NMR spectra can be achieved in some cases only by using several measurement techniques.

Nitrogen-15 is an ideal nucleus for the application of methods based on polarization transfer such as

**Table 2** Comparison of theoretical sensitivities of various NMR experiments as a function of different excitation and detections<sup>a</sup>

Experiment	S/N <sup>b</sup>	Amplification factor	<sup>15</sup> N <sup>c</sup>
(a) Direct observation	$\gamma_{\text{N}}(\gamma_{\text{N}})^{3/2}$		1.0
(b) INEPT	$\gamma_{\text{H}}(\gamma_{\text{N}})^{3/2}$		
Compared with (a)		$(\gamma_{\text{H}}/\gamma_{\text{N}})^{3/2}$	9.9
(c) Inverse INEPT	$\gamma_{\text{N}}(\gamma_{\text{H}})^{3/2}$		
Compared with (a)		$(\gamma_{\text{H}}/\gamma_{\text{N}})^{3/2}$	31.0
Compared with (b)		$(\gamma_{\text{H}}/\gamma_{\text{N}})^{1/2}$	3.1
(d) Inverse shift correlation	$\gamma_{\text{H}}(\gamma_{\text{H}})^{3/2}$		
Compared with (a)		$(\gamma_{\text{H}}/\gamma_{\text{N}})^{5/2}$	306.0
Compared with (b)		$(\gamma_{\text{H}}/\gamma_{\text{N}})^{3/2}$	31.0

<sup>a</sup>From Kessler H, Gehrke M, and Griesinger C (1988) Two-dimensional NMR spectroscopy: background and overview of the experiments. *Angewandte Chemie (International Edition in English)* 27: 490–536.<sup>b</sup>Signal-to-noise ratio.<sup>c</sup>Relative sensitivity.

intensive nuclei enhanced by polarization transfer (INEPT) or distortionless enhancement by polarization transfer (DEPT). The INEPT technique is preferred, especially when polarization transfer is based in small long-range coupling constants, because the sequence is shorter and the loss of magnetization during the evolution and refocusing period is lower. Table 2 shows the amplification factors that can be achieved with respect to the standard experiment. The pulse repetition time in these one-dimensional pulse sequences is governed by much shorter proton relaxation times than those of <sup>15</sup>N, which leads to an additional improvement in the signal-to-noise ratio in a given time compared with standard experiments. Both proton-coupled and proton-decoupled spectra can be obtained using the above-mentioned techniques, depending on a modification of sequences (Figure 1).

Two-dimensional (2D) <sup>1</sup>H–<sup>15</sup>N shift-correlated spectra are used for the assignment of <sup>15</sup>N resonance based on known <sup>1</sup>H chemical shifts, particularly in complicated synthetic and natural products. Measurements via both one-bond and long-range coupling constants *J* (<sup>15</sup>N, <sup>1</sup>H) are possible. Classical 2D

**Figure 1**  $^{15}\text{N}$  NMR (50, 76 MHz) spectra of formamide: normal spectrum with proton noise decoupling (upper trace), INEPT spectrum (middle trace), and DEPT spectrum (bottom trace) ( $^1J(^{15}\text{N}, ^1\text{H}) = 90.3$  and  $88.0$  Hz,  $^2J(^{15}\text{N}, ^1\text{H}) = 13.6$  Hz).

$^1\text{H}$ - $^{15}\text{N}$  shift-correlated experiments suffer from the low sensitivity of the  $^{15}\text{N}$  nucleus, but this can be overcome by the use of inverse detection. A special probe is required for this type of experiment with the orientation of the coils in the probe reversed, i.e., the proton coil is closer to the sample. Inverse detection measurements give the highest amplification factor (Table 2) and very dilute solutions of complex molecules can be measured even at the natural abundance level of  $^{15}\text{N}$ .

The problem of  $^1\text{H}$ - $^{15}\text{N}$  shift-correlated spectra measurements using inverse detection consists in the fact that 99.635% of signal intensity corresponding to the  $^1\text{H}$ - $^{14}\text{N}$  pairs must be very efficiently suppressed and only 0.365% of original proton signal intensity corresponding to the  $^1\text{H}$ - $^{15}\text{N}$  pairs is observed. Magnetic field gradients are successfully used for this purpose. There are three very important reasons for their application: (1) gradients are used to suppress  $t_1$  noise and are highly desirable for  $^1\text{H}$ - $^{15}\text{N}$  shift-correlated spectra measurements at the natural abundance of the  $^{15}\text{N}$  isotope; (2) they can be used to select coherence pathways; and (3) magnetic field gradients are used for solvent suppression, which is especially important when biological samples at low concentrations (typically polypeptides, etc.) are measured in a mixture of 90%  $\text{H}_2\text{O}$ /10%  $\text{D}_2\text{O}$ .

Probably the most important benefit obtained from an application of magnetic field gradients comes from  $t_1$ -noise suppression. Magnetic field gradients are used very frequently in practically all pulse sequences starting from simple  $^1\text{H}$ - $^{15}\text{N}$  shift-correlated experiments to very sophisticated two- and especially three-dimensional measurements.

From the viewpoint of solid-state NMR,  $^{15}\text{N}$  is one among the 'dilute' nuclear spin systems. The  $^{15}\text{N}$  cross-polarization-magic angle spinning (CP-MAS) NMR technique is recommended so that the sensitivity of measurement may be increased and the signals narrowed.

The use of  $^{15}\text{N}$  enrichment (from the natural abundance of 0.365% up to ~100% of  $^{15}\text{N}$ ) should be mentioned as a tool for (1) a considerably shortening experimental time and (2) unequivocal signal assignment (provided selective labeling has been performed).

Nitrogen-15 chemical shifts are mostly referenced to an external standard, usually nitromethane, placed in a coaxial capillary. The position of nitromethane resonance produces mostly negative values of  $^{15}\text{N}$  chemical shifts. A wide variety of other standards have been used ( $\text{NH}_3$ ,  $\text{NH}_4\text{Cl}$ ,  $\text{NH}_4\text{NO}_3$ ,  $\text{HNO}_3$ , etc.). Liquid ammonia is frequently used, as it has the advantage that practically all  $^{15}\text{N}$  chemical shifts are positive. The difference in  $^{15}\text{N}$  chemical shifts of nitromethane (being shifted to the higher frequency) and liquid ammonia is 381.7 ppm. In the solid state, the  $^{15}\text{N}$  chemical shifts are referenced to a standard solid compound by sample replacement. Two sign conventions have been used. High-frequency shifts with respect to a standard are taken as (1) positive in agreement with the IUPAC recommendation or (2) negative in line with shielding constants.

### Illustrative Examples of the Use of $^{15}\text{N}$ NMR in Structure Determination

The  $^{15}\text{N}$  NMR spectrum of 4,6-dinitro-2-nitrosoaniline (Figure 2) is a good example of the use of the technique as the compound shows nearly the whole range of  $^{15}\text{N}$  chemical shifts (~900 ppm for diamagnetic compounds). Typical ranges of  $^{15}\text{N}$  NMR chemical shifts in some nitrogen-containing compounds are collected in Table 3. Half-line widths in  $^{15}\text{N}$  NMR spectra obtained from compounds in solution are usually very narrow (nearly several hundredths or tenths of ppm) and many types of functional groups can be distinguished directly.

The protonation shifts are typical of various compounds: slight deshielding in alkyl amines (<20 ppm), usually slight shielding in arylamines

and strong shielding ( $>100$  ppm) in compounds containing the arrangements  $\text{--N=}$  and  $\equiv\text{N}$  have been observed. In compounds containing several

**Figure 2**  $^{15}\text{N}$  NMR (10.17 MHz) spectrum of 4,6-dinitro-3-nitrosoaniline in dimethyl sulfoxide ( $\delta(^{15}\text{N}) = -473.9$  (NO), 0.0) ( $\text{CH}_3\text{NO}_2$ , reference compound,  $-14.4$  and  $-14.9$  ( $2 \times \text{NO}_2$ ) and  $-293.9$  ( $\text{NH}_2$ )). (Macháček V, Hassanien MMM, Štěrba V, and Lyčka A (1987) Formation of 4,6-dinitro-2-nitrosoaniline by intermolecular redox reaction of esters and amides of 2-(2,4,6-trinitroaniline) carboxylic acids. *Journal of the Chemical Society, Perkin Transaction II*, p. 869; reproduced by permission of The Royal Society of Chemistry.)

nitrogen atoms it is possible to determine site(s) of protonation and  $\text{pK}_a$  from the pH dependence of the  $^{15}\text{N}$  chemical shifts.

Nitrogen-15 chemical shifts are an ideal tool for tautomeric equilibria studies. Nitrogen atoms are directly involved in various tautomeric systems and  $^{15}\text{N}$  chemical shifts reflect the changes in equilibria in a much better way than either  $^1\text{H}$  or  $^{13}\text{C}$  chemical shifts. Differences in  $\delta^{15}\text{N}$  of pure tautomeric forms can reach several hundreds of ppm (nitroso-isonitroso, azo-hydrazone tautomerism, etc.). Similarly, large changes in  $^{15}\text{N}$  chemical shifts with respect to those in parent compounds have been observed in metal complexes, these changes being both positive and negative.

A set of typical coupling constants  $^nJ(^{15}\text{N}, ^1\text{H})$  and  $^nJ(^{15}\text{N}, \text{X})$ , which can be used both for assignment purpose as well as for polarization transfer techniques, are shown in Table 4.  $^{15}\text{N}$  enrichment is usually necessary for measurements of  $^nJ(^{15}\text{N}, \text{X})$  coupling constants when X nuclei are of low natural abundance. Some coupling constants  $^nJ(^{15}\text{N}, \text{X})$  describe the 's character' of bonds, reflect coordination, site of protonation, tautomeric equilibria, or solvent effects, and are very useful in *syn-anti* and *cis-trans* stereochemistry and conformational analysis. In many cases, the absolute values of the  $^nJ(^{15}\text{N}, \text{X})$  coupling constants for characteristics to be distinguished represent the lowest and highest values of a typical range and the differentiation and/or relative quantification of a property is easy.

**Table 3** Characteristic ranges of  $^{15}\text{N}$  chemical shifts in various types of compounds<sup>a</sup>

Compound	$\delta(^{15}\text{N})$	Compound	$\delta(^{15}\text{N})$
Alkylamines	$-310$ to $-380$	Triazenes $\text{RN}=\text{N}-\text{NR}'_2$

$\text{R}_2\text{N}-\text{NO}_2$		$\text{R}_2\text{C}=\text{NOH}$	$0$ to $-55$
$\text{R}_2\text{N}-$	$-100$ to $-220$	$\text{M}-\text{NO}$ (linear)	$100$ to $-80$
$-\text{NO}_2$	$-20$ to $-40$	$\text{M}-\text{NO}$ (bent)	$850$ to $380$

<sup>a</sup> Referred to nitromethane ( $\delta=0.0$ ), positive values denote shifts to higher frequency.

<sup>b</sup> Pyrrole-type of nitrogen,  $\delta(^{15}\text{N})$  of pyridine-type of nitrogen:  $0$  to  $-140$ .

Both  $^{15}\text{N}$  chemical shifts and  $^nJ(^{15}\text{N}, \text{X})$  coupling constants are very sensitive to the presence of a lone pair on nitrogen, to its geometrical orientation, and to  $\pi$ -delocalization. Correlation analyses of  $\delta(^{15}\text{N})$  and  $^nJ(^{15}\text{N}, \text{X})$  and various physical, topological, and semiempirical parameters have been computed.

Two-dimensional  $^1\text{H}$ - $^{15}\text{N}$  shift-correlated spectra have been used in the assignment of polypeptides and similar compounds. The inverse detection technique (Figure 3) enables the measurements of very dilute solutions of compounds having high relative molecular mass. The experiment was optimized for the  $^1J(^{15}\text{N}, \text{H})$  coupling constant ( $\sim 90$  Hz) and magnetic field gradients were used in the pulse sequence. Application of magnetic field gradients is of key

importance in  $^1\text{H}$ - $^{15}\text{N}$  correlation experiments optimized for long-range  $^nJ(^{15}\text{N}, \text{H})$  coupling constants ( $n \geq 2$ ,  $^nJ(^{15}\text{N}, ^1\text{H}) \leq 16$  Hz). Figure 4 shows a 2D gradient selected  $^1\text{H}$ - $^{15}\text{N}$  HMBC spectrum of 2-benzyl-1-butyl-2,3-dihydro-imidazo[1,5-*c*]quinazoline-3,5-dione optimized for the long-range coupling constant  $^nJ(^{15}\text{N}, ^1\text{H}) = 7$  Hz. In addition to the values of  $^{15}\text{N}$  chemical shifts, correlations of an appropriate nitrogen with several protons can be

**Table 4** Absolute values of coupling constants  $^nJ(^{15}\text{N}, \text{X})$  (Hz)

(Spectrum taken from Veverka V, Bauerová H, Zábranský A, Pichová I, and Hrabal R (2001). *Journal of Biomolecular NMR* 20: 291–292, with permission.)

**Figure 4** (A) Two-dimensional gradient selected  $^1\text{H}$ - $^{15}\text{N}$  HMBC NMR spectrum of 2-benzyl-1-butyl-2,3-dihydro-imidazo[1,5-*c*]quinazoline-3,5-dione optimized for a long-range coupling constant  $^nJ(^{15}\text{N}, ^1\text{H}) = 7$  Hz. The NH proton correlates with both nitrogens of NH group (giving a clearly visible doublet due to  $^1J(^{15}\text{N}, ^1\text{H})$ ,  $\delta(^{15}\text{NH}) = -264.6$ , second cross-peak belongs to the correlation with aromatic proton from *peri* position) and nitrogen via  $^3J(^{15}\text{N}, ^1\text{H})$  from  $\text{HN-CO-N}$  ( $\delta(^{15}\text{N}) = -232.0$ ). Third nitrogen correlates with methylene protons of both butyl and benzyl groups ( $\delta(^{15}\text{N}) = -241.8$ ). (B) Structure of 2-benzyl-1-butyl-2,3-dihydro-imidazo[1,5-*c*]quinazoline-3,5-dione. (Spectrum taken from Klásek A, Kořístek K, Lyčka A, and Holčápek M (2003) *Tetrahedron* 59: 1283–1288, with permission.)

used very successfully in structure elucidation as well as in unequivocal assignment of  $^{15}\text{N}$  chemical shifts.

Three-dimensional spectra allow the spatial structure of complex molecules, e.g., proteins, to be studied (Figure 5).

Single crystals, crystalline, or amorphous powders and whole biological systems have been studied in the solid state by means of  $^{15}\text{N}$  NMR spectroscopy. The proton-decoupled  $^{15}\text{N}$  NMR powder pattern, measured in the solid state without rotation of a

**Figure 5** A part of the 3D NOESY  $^1\text{H}$ - $^{15}\text{N}$  HSQC NMR spectrum of uniformly labeled protein showing NOE connectivities of the NH to aliphatic protons;  $1\text{ mmol}^{-1}$  sample of the 79 amino acids fragment of transcriptional activator Jun in 90%  $\text{H}_2\text{O}/10\%$   $\text{D}_2\text{O}$  that formed a stable dimer (relative mass  $\approx 18000$ ) under given conditions. Total measuring time on a Bruker AMX 500 spectrometer equipped with a triple resonance probe and a gradient accessory was 60 h. (Reproduced with permission from Sklenář V, Piotto M, Lepik R, and Saudek V (1984); unpublished results.)

sample, arises from chemical shift anisotropy and covers a range of  $10^3$  to  $10^4$  Hz. Relatively very narrow signals can be obtained in  $^{15}\text{N}$  CP-MAS NMR spectra (Figure 6). This allows the study in the solid state of problems that are also studied in solutions. The isotropic peaks are flanked by spinning sidebands, the intensities of these side-band resonances correspond to the MAS rate. Great progress in improvement of instrumentation for solid state, very short pulses, effective decouplers, very high MAS rates, and pulse sequences development allow studying rather complex molecules including biological systems to be studied.

Dynamic solid-state  $^{15}\text{N}$  NMR studies have been performed to study proton transfer in, e.g., porphine derivatives. Line-shape analysis has provided rates of proton exchange that differ greatly from case to case and that are often very different when comparing solution and solid-state data.

Temperature changes of  $^{15}\text{N}$  chemical shifts in the solid state have been used to characterize tautomeric equilibria.

High-resolution 2D dipolar chemical shift experiments in the solid state permit the determination of bond distances  $^{15}\text{N}$ - $^1\text{H}$  and  $^{15}\text{N}$ - $^{13}\text{C}$ .

## Quantitative Analysis

The application of  $^{15}\text{N}$  NMR spectroscopy in quantitative analysis is limited to special cases because of the complicated relaxation mechanisms of the  $^{15}\text{N}$  nucleus and its negative magnetogyric ratio. It is extremely difficult to find experimental conditions providing intensities of  $^{15}\text{N}$  NMR signals exactly proportional to the relative abundance of compounds containing various types of nitrogens in their molecules.

**Figure 6** (A)  $^{15}\text{N}$  CP-MAS NMR (20.28 MHz, magic-angle spinning frequency 5 kHz) spectrum of  $^{15}\text{N}_\alpha^{15}\text{N}_\beta$  doubly enriched 3-methyl-1-phenyl-4,5-dione 4-phenylhydrazine.  $\delta(^{15}\text{N}_\alpha) = -222.9$ ,  $\delta(^{15}\text{N}_\beta) = -37.0$ . The asterisks denote spinning sidebands. (B) Structure of 3-methyl-1-phenyl-4,5-dione 4-phenylhydrazine.

Probably the best approach makes use of gated decoupling in order to suppress the NOE effect, long relaxation times, and an effective relaxation reagent with a nonspecific effect for all the nitrogens present. Even traces of paramagnetic impurities in sample, which act preferentially on certain molecular structures, can make quantitative analysis impossible.

On the other hand,  $^{15}\text{N}$  chemical shifts and  $^nJ(^{15}\text{N}, \text{X})$  (especially  $^nJ(^{15}\text{N}, ^1\text{H})$ ) can be used successfully for relative quantification, e.g., tautomeric equilibria, in cases of fast exchange on the NMR time scale when average values of the above-mentioned characteristics are observed experimentally.

## Introduction

Phosphorus occurs predominantly as the isotope  $^{31}\text{P}$ , which has a nuclear spin value of 1/2 and is therefore visible in nuclear magnetic resonance (NMR) spectrometry. Phosphorus NMR ( $^{31}\text{P}$  NMR) has been in use since the development of multinuclear, high-field Fourier-transform instruments in the late 1970s. The  $^{31}\text{P}$  NMR method is widely used, with both one-dimensional (1D) and multidimensional techniques, in such diverse areas as the characterization of organic and inorganic molecular structures, the analysis of biological fluids, the determination of intracellular pH, the noninvasive study of intact tissues and organs, and quantitative assays of industrial

products. In many routine applications,  $^{31}\text{P}$  NMR can now be carried out in a fully automated manner. Used in conjunction with other NMR-visible nuclei, the quantitation and full structure elucidation of a host of disparate species is possible. This article provides an overview of  $^{31}\text{P}$  NMR technology and some of its major applications.

## General Properties and Chemical Shifts

The chemical shift ( $\delta$ ) is a sensitive indicator of the chemical environment around the phosphorus atom. It relates closely to the molecular structure, and under some circumstances even facilitates stereochemical identification. The unique chemistry of phosphorus-containing materials is partially attributable to the variable oxidation state of  $^{31}\text{P}$ , the participation of d orbitals in bonding, and the ability of the phosphorus atom to vary its coordination number between 1 and 6.

Probably the best approach makes use of gated decoupling in order to suppress the NOE effect, long relaxation times, and an effective relaxation reagent with a nonspecific effect for all the nitrogens present. Even traces of paramagnetic impurities in sample, which act preferentially on certain molecular structures, can make quantitative analysis impossible.

On the other hand,  $^{15}\text{N}$  chemical shifts and  $^nJ(^{15}\text{N}, \text{X})$  (especially  $^nJ(^{15}\text{N}, ^1\text{H})$ ) can be used successfully for relative quantification, e.g., tautomeric equilibria, in cases of fast exchange on the NMR time scale when average values of the above-mentioned characteristics are observed experimentally.

Phosphorus compounds give resonances in characteristic ranges depending primarily on the oxidation state and coordination number of the phosphorus atoms present (Table 1). Chemical shifts also depend on the pH, concentration, and salt content of the solution, solvent effects, and the electronegativity of any substituents. Since the phosphorus atom is a comparatively reactive center, it can usually

be found at or near an active site of interest. In general, phosphorus chemical shifts are referenced to an external standard. This requires minor corrections to be made because of differences in the bulk properties of the samples. The primary <sup>31</sup>P reference is 85% phosphoric acid placed in a sealed spherical container or cylindrical capillary tube. A number of secondary external and internal standards have been used

for specialized applications, including  $0.2 \text{ mol l}^{-1}$  phosphoric acid in 14% aqueous perchloric acid, aqueous disodium methylenediphosphonate, deuterated phosphoric acid ( $\text{D}_3\text{PO}_4$ ), trimethyl phosphine oxide, trimethylphosphonate,  $\text{P}_4\text{O}_6$ , phosphocreatine, and hexachlorocyclotriphosphazene in  $\text{C}_6\text{D}_6$ .

The chemical shift is sensitive to changes in the chemical environment, as is spin-spin coupling ( $J$ ). Examples of this sensitivity are listed in Table 1, which also gives examples of the wide variety of coordination numbers and oxidation states of phosphorus.  $^{31}\text{P}$  chemical shifts cover a wide range. Dissolved or gaseous diamagnetic phosphorus compounds span  $\sim 1900$  ppm. For dissolved paramagnetic phosphorus compounds, this range extends to  $\sim 2600$  ppm, with  $\text{OsCl}_4\text{P}[(n\text{-C}_4\text{H}_9)_2\text{C}_6\text{H}_5]_2$  observed at  $\sim 1219$  ppm. While it is beyond the scope of this article to provide a comprehensive list of  $^{31}\text{P}$  chemical shifts, further details can be found in the books and articles listed in the bibliography. The chemical shift is not the only parameter available for probing the molecular environment of a phosphorus atom. Pairs of phosphorus atoms can couple to each other, and individual phosphorus atoms can couple to  $^{13}\text{C}$  and  $^1\text{H}$  atoms.  $^{31}\text{P}$ - $^{13}\text{C}$  and  $^{31}\text{P}$ - $^1\text{H}$  couplings are sensitive to the stereochemical relationship between the coupling nuclei. Used together with carbon chemical shifts, the conformation and stereochemical features of many chemical systems can be deduced.  $^1\text{H}$ - $^{31}\text{P}$  couplings have been studied through one to four bonds and exhibit a dependence on the molecular conformation and geometry. Examples of the different types of couplings are shown in Table 2. The use of homonuclear and heteronuclear coupling constants and multinuclear (e.g.,  $^{31}\text{P}$ ,  $^1\text{H}$ , and  $^{13}\text{C}$ ) NMR data allows the structure of monophosphorus

and polyphosphorus compounds to be determined fully.

## Instrumentation and Sample Requirements for $^{31}\text{P}$ NMR

Many contemporary NMR spectrometers are capable of operating in multinuclear mode, and  $^{31}\text{P}$  NMR can be performed in most cases simply by tuning the NMR probe to the phosphorus frequency and carrying out the necessary calibrations. Common  $^{31}\text{P}$  resonance frequencies (MHz) and magnetic field strengths (T) are 80.96/4.7, 121.44/7.05, 161.92/9.4, and 202.4/11.75.

The signal-to-noise ratio is dependent on many variables, not all of which can be controlled by the operator. These include the volume of sample, the magnetic field strength ( $B_0$ ), the magnetic probe design, spectral accumulation time, relaxation times  $T_1$  and  $T_2$ , and sample concentration. With the wide range of available instruments,  $^{31}\text{P}$  NMR can be performed on samples ranging in size from a few microliters, through a few tenths of a milliliter to several milliliters, using respectively a microprobe, a 5 mm probe, and a 10 mm probe. When the operator is limited to a given sample and a single type of instrument, the most sensitive probe for  $^{31}\text{P}$  measurements should be chosen, and the sample should be concentrated as much as possible, since this helps to decrease accumulation time and improve sample throughput. Nevertheless, reasonable spectra can be obtained with sample concentrations in the range  $1\text{--}5 \text{ mmol l}^{-1}$ .

Faced with dilute samples, proper presentation of the sample and accurate spectrometer calibrations are particularly important. The sample should be mobile rather than bound, deoxygenated, and free of particulates. The removal of particulates by filtration makes a significant improvement to spectral quality. High-resolution solution work usually requires dissolution in a deuterated solvent for instrumental locking. However, excellent spectra can often be obtained in protonated solvents in the presence of a concentrically placed sealed capillary tube containing the deuterated solvent. This approach is unsuitable for intact biological samples where the NMR probe and coil assembly is designed around the specimen.

As with other nuclei, the highest  $^{31}\text{P}$  signal-to-noise ratio is obtained when the following operations are performed:

- Optimization of magnetic field homogeneity (shimming).
- Calibration of the observe coil  $90^\circ$  pulse width ( $\pi/2$ ).

**Table 2** Typical  $^{31}\text{P}$  coupling constants

Compound	Phosphorus atom coupling constant (Hz, absolute value)
$\text{PH}_3$	$186 J_{\text{PH}}$

 E  $R_1 = \text{Et}$   $R_2 = i\text{-Pr}$   
 F  $R_1 = R_2 = i\text{-Pr}$

## Applications of $^{31}\text{P}$ NMR Spectroscopy

### One-Dimensional Methods

Useful information can often be obtained by collecting a normal 1D survey (semiquantitative) spectrum employing gated proton decoupling and rapid repetition conditions (i.e., a flip angle  $< 90^\circ$  and a relatively short recycle time). Species can be identified by the observation of chemical shifts and relative concentrations from integration of the resonances.

In many cases, the 1D spectra are sufficiently complicated to prohibit a straightforward analysis. For example, **Figure 1A** shows the reaction products from the alcoholysis of  $\text{P}_4\text{S}_{10}$  with methanol, ethanol, and isopropanol. In this case, the selective use of techniques commonly employed in  $^{13}\text{C}$  NMR, such as the attached proton test (APT), distortionless enhancement through polarization transfer (DEPT), and insensitive nucleus enhancement through polarization transfer (INEPT), can yield simplified results. These methods facilitate the identification of appropriate functional groups surrounding the  $^{31}\text{P}$  atom. Coding of the heteronuclear coupling into an observable intensity modulation of the  $^{31}\text{P}$  signals is achieved using appropriately chosen delays in the pulse sequences and decoupler gating. The intensity of the observed  $^{31}\text{P}$  signal in these experiments depends on the number of protons, the heteronuclear coupling constant, and pulse delays (often represented by  $\tau$ ) as is shown in the APT spectrum in **Figure 1B**. Appropriate analysis of the intensity profiles as a function of the delays then results in a complete identification of the complex mixture. Further verification can be achieved by collecting the  $^1\text{H}$ -coupled  $^{31}\text{P}$  spectrum. Little use has been made of the INEPT method in  $^{31}\text{P}$  NMR experiments because optimization of the correct timing intervals is difficult due to the presence of numerous  $^1\text{H}$ - $^{31}\text{P}$  couplings. However, a greater than 10-fold enhancement can result from the use of polarization transfer procedures. This translates into a factor of 100 or more in time savings during data accumulation. However, where small (i.e., long-range) coupling constants are involved, longer delays are necessary in the pulse sequence. During these delays, the observable signal diminishes due to relaxation processes, resulting in lower signal-to-noise ratios. In

**Figure 1** (A) 32.44 MHz  $^{31}\text{P}$  spectrum of the alcoholysis products of  $\text{P}_4\text{S}_{10}$  with methanol, ethanol, and isopropanol. The sample is dissolved in toluene, with external  $\text{C}_6\text{D}_6$  as the field frequency lock. (B) The  $^{31}\text{P}$  APT spectrum of the same mixture, showing the encoding of functional group and multiplicity information into the intensity and phase of the resonances. (Reprinted from Jancke H, Radeglia R, Neels J, and Porzel A (1984) Application of the attached proton test technique in  $^{31}\text{P}$  NMR spectroscopy. *Organic Magnetic Resonance* 22: 376–378; © Wiley.)

such cases, multinuclear multidimensional techniques become more suitable.

### Two-Dimensional Methods

**Homonuclear NMR** Structural elucidation becomes much more difficult as spectral complexity increases. Under these circumstances, proton NMR spectroscopy has benefited considerably from the use of 2D NMR techniques. For example, homonuclear correlation spectroscopy (COSY) identifies spin-coupled pairs of nuclei as well as spin-coupled networks of nuclei in a molecule, even without prior structural information. The 2D  $J$ -resolved spectroscopy method permits even highly overlapping resonances to be resolved into readily interpretable multiplets. This enables chemical shift assignments to be made in a very straightforward manner. Both of

these techniques can easily be applied to  $^{31}\text{P}$  NMR, with enormous gains in the detail of spectral information.

Figure 2A shows a  $^{31}\text{P}$ - $^{31}\text{P}$  COSY spectrum of a mixture of phosphate metabolites (ATP, AMP, or orthophosphate, and pyrophosphate, at two different pH values). The 1D spectrum shown in Figure 2B is also present along the diagonal of the contour plot. The off-diagonal elements, or cross-peaks, connect pairs of spin-coupled phosphorus resonances to each other, allowing the entire network to be rapidly assigned. Such a straightforward analysis is not

possible from the congested 1D spectrum. Along with connectivity information, the pH of the solution can be measured noninvasively from the chemical shift of the inorganic phosphate resonance.

Similarly, homonuclear  $^{31}\text{P}$ - $^{31}\text{P}$  2D  $J$ -resolved spectroscopy helps simplify even the most crowded spectra. The 1D spectrum of a dissolved phosphate glass of average chain length  $n=4.1$  is shown along the top of Figure 3. Even at 161.9 MHz, the peaks overlap significantly. Carrying out a 2D  $J$ -resolved experiment on this sample resolves the individual species clearly, with a monotonic increase in

**Figure 2** Two-dimensional homonuclear correlated spectrum (COSY) for a mixture of phosphate metabolites (A) in separate pH compartments. The 1D experiment (B) is shown below the  $^{31}\text{P}$ - $^{31}\text{P}$  COSY spectrum. The sample consisted of concentric NMR tubes with the inside pH at 7.5 (designated by capital letters) and the outside at pH 6.5 (lower-case letters). The diagonal peaks labelled D-d, E-e, F-f and G-g, represent the phosphate resonances of ATP ( $\beta$ -phosphate), AMP, orthophosphate, and pyrophosphate, respectively. The cross-peak A-a correlates the  $\alpha$ - and  $\beta$ -phosphorous resonances of ADP, B-b correlates the  $\gamma$ - and  $\beta$ -resonances of ATP, and C-c correlates the  $\alpha$ - and  $\beta$ -resonances of ATP. The resonances were broadened by the addition of  $\text{GdCl}_3$ . (Reprinted from Van Divender JM and Hutton WC (1982) The application of homonuclear two-dimensional chemical shift correlation maps to the  $^{31}\text{P}$  nuclear magnetic resonances of mixtures of nucleotides involved in cellular bioenergetic process. *Journal of Magnetic Resonances* 48: 272-279.)

**Figure 3** A  $^{31}\text{P}$ – $^{31}\text{P}$  homonuclear 2D  $J$ -resolved NMR spectrum of a dissolved sodium phosphate glass with  $\bar{n} = 4.1$  (shown at the bottom). The characteristic  $J$ -coupling for each species is observed, causing extensive overlap in the corresponding 1D spectrum shown at the top. The vast simplification obtained by projecting the 2D  $J$ -resolved spectrum vertically onto the chemical shift axis (middle spectrum) clearly delineates the effectively broadband decoupled resonances. All spectra were accumulated at 161.9 MHz using a 5% (m/m) phosphate solution in  $\text{H}_2\text{O}$  with a  $\text{D}_2\text{O}$  insert for locking purposes.

chemical shift observed with increasing chain length,  $P_n$ . The  $F_1$  axis displays the coupling constant information, while the  $F_2$  axis shows the chemical shift of each species. Further simplification is achieved by

projecting the spectrum onto the chemical shift axis, which is shown above the contour plot. This effectively decouples all the resonances from each other, yielding individually resolved singlets.

**Heteronuclear NMR** As discussed above, complex spectral information can be simplified greatly by resolving  $^{31}\text{P}$ – $^{31}\text{P}$  homonuclear interactions into two dimensions while simultaneously increasing the information content of the spectra. Using additional 2D modes available on the majority of current spectrometers, further information can be obtained by correlating individual phosphorus resonance alignments with their respective protons. In these heteronuclear shift-correlated experiments, the nucleus that is detected can be either  $^1\text{H}$  or  $^{31}\text{P}$ .

Much information can be gained by observing the phosphorus nucleus in these experiments. One approach known as  $^1\text{H}$ -detected heteronuclear multiple quantum coherence (HMQC) is shown in Figure 4, applied to the detection of  $^{31}\text{P}$  resonances in d(TGGT)Pt(en), an oligodeoxyribonucleotide adduct of an anticancer drug. In this example, each  $^{31}\text{P}$  resonance was uniquely correlated with the corresponding  $\text{H}_3'$  resonance in the preceding nucleotide residue; the  $\text{H}_5'$ ,  $\text{H}_5''$  resonances were also resolved

**Figure 4** HMQC contour plot and corresponding  $^{31}\text{P}$  (top) and  $^1\text{H}$  (side) traces for a  $5\text{ mmol l}^{-1}$   $\text{D}_2\text{O}$  solution of d(TGGT)Pt(en) at 400 MHz ( $^1\text{H}$ ), 20°C and pH 7.1. (Reprinted from Byrd RA, Summers MF, Zon G, Fouts CS, and Marzilli LG (1986) A new approach for assigning  $^{31}\text{P}$  NMR signals and correlating adjacent nucleotide deoxyribose moieties via  $^1\text{H}$ -detected multiple-quantum NMR. Application to the adduct of d(TGGT) with the anticancer agent (ethylenediamine)dichloroplatinum. *Journal of the American Chemical Society* 108: 504–505. © 1986, American Chemical Society.)

for the  $^{31}\text{P}$  resonances at  $-2.96$  ppm. Subsequent comparison with 2D nuclear Overhauser effect (NOE) studies and variable temperature work provided unambiguous assignments of all the  $^{31}\text{P}$  resonances.

Heteronuclear shift correlation is not restricted to  $^1\text{H}$  and  $^{31}\text{P}$  alone.  $^{31}\text{P}$ -detected experiments permit ready observation of rare nuclei, such as  $^{183}\text{W}$  and  $^{57}\text{Fe}$ , which are normally difficult to observe. This approach has been used with success for the observation of organometallic phosphorus tungsten(IV), rhodium(I), iron(0), iron(II), and nickel(0) complexes. Indirect observation of insensitive spin 1/2 nuclei offers tremendous gains in sensitivity over direct observation.

## Analytical Aspects

Using many of the techniques often applied to the study of  $^1\text{H}$  and  $^{13}\text{C}$ ,  $^{31}\text{P}$  NMR is a powerful tool for structure elucidation. Observation of the  $^{31}\text{P}$  nucleus opens yet another realm of study – quantitation of the individual species that were previously identified using the methods described above. Quantitation requires the optimization of observation conditions such as pulse width, recycle delay and decoupler gating, as well as determination of the inherent relaxation time of the nucleus,  $T_1$ . Relative quantitation is then easily achieved, with the area under any peak directly proportional to the concentration of the species represented by that resonance. Comparison of the resulting integrals with that of integral standards yields absolute quantities. The precision of phosphate assays by  $^{31}\text{P}$  NMR is consistently within 0.2–0.6%, comparable with results obtained using chromatographic methods.

Indeed,  $^{31}\text{P}$  NMR is widely used in a quantitative fashion. Computer-controlled and automated instruments, used in combination with robotic sample changers, make the large number of analytical samples much more manageable. With customized software, the spectrometer can automatically accumulate and store data, perform the Fourier transform and integration, calculate the relative distribution of species present and generate the analytical report. As an example, Figure 5 shows the output from a routine oligophosphate assay.

## Biological and *In Vivo* Applications

$^{31}\text{P}$  NMR has also been widely used in biological investigations. High-resolution NMR has been used increasingly for the analysis of biological samples and tissues, allowing the identification and quantitation of all  $^{31}\text{P}$ -containing species without further

**Figure 5** 121 MHz  $^{31}\text{P}$  spectrum of a 5% (m/m)  $\text{H}_2\text{O}$  solution of oligophosphates, with a  $\text{H}_3\text{PO}_4\text{-D}_2\text{O}$  capillary inserted for locking purposes. The spectrum and analytical report were automatically generated after making only a few menu choices and placing the sample into the robot sample tray.

purification. NMR has been used to study  $^{31}\text{P}$ -containing molecules such as oligonucleotides, nucleotides, proteins, and phosphosugars. Positive resonance assignments are obtained even in cases of high spectral complexity, such as the phosphate metabolite mixture shown in Figure 2.

The invention of the surface coil and the development of NMR probes containing life-support systems have made it possible to observe high-energy phosphates in intact tissues and whole organisms.  $^{31}\text{P}$  NMR has been used for the safe, noninvasive detection of disease states in tissues without risk to the patient. Metabolic products soluble in the cytoplasm of skeletal muscle, heart, kidney, brain, and eye have all been qualitatively observed and identified. With the appropriate use of standards, determination of relaxation times, and performance of the necessary instrument calibrations, quantitative results can be comparable to those obtained in wet-chemical assays. The protonation/deprotonation equilibrium of phosphates influences the  $^{31}\text{P}$  chemical shift, facilitating the noninvasive determination of tissue pH.

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy is one of the most powerful instruments in determining the structure and properties of an organometallic compound because of the sensitivity of the chemical shift to difference in geometry. Also, the term ‘organometallic’ seems suitable only for compounds having at least one carbon atom directly linked to a metal, and the scientific community uses this term also for compounds in which organic groups are bonded to nonmetallic elements such as boron, silicon, and phosphorus. In the first edition of the *Encyclopedia of Analytical Science*, the discussion of the application of NMR spectroscopy to organometallic chemistry has been mainly directed to the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, here the discussion will be addressed mainly on multinuclear NMR spectroscopy.

NMR spectra of nuclei having a spin quantum number  $I = 1/2$  are generally more easy to investigate due to a coupling behavior similar to that of  $^1\text{H}$ . However, some factors, that could make it difficult to record and assign an NMR spectrum, need to be considered: (1) isotopic abundance, (2) sensitivity, (3) nuclear quadrupole, and (4) relaxation time. For example, small molecules having nuclei  $1/2$  exhibit generally sharp lines ( $W_{1/2} = 0\text{--}10\text{ Hz}$ ), but if the nuclei interacts weakly with environments, long relaxation times, that make the detection of signals very difficult, can occur (the  $T_1$  for  $^{109}\text{Ag}$  is up to 1000 s). Nuclei having spin with  $I$  in the range  $1\text{--}9/2$  are also suitable for an NMR investigation; however, these nuclei possess a quadrupole moment (deviation from spherical charge distribution) which produces extremely short relaxation time and extremely large linewidth  $W_{1/2}$  (up to 50 Hz). If the compounds have

low molecular weight (small  $\tau_c$ ) or if the nuclei are embedded in ligand field of cubic (tetrahedral, octahedral) symmetry ( $q_{zz}$  blocked), narrow lines have been generally observed (eqn [1]).

$$W_{1/2} = \frac{(2I + 3)Q^2 q_{zz}^2 \tau_c}{I^2(2I - 1)} \quad [1]$$

where  $Q$  is the quadrupole moment;  $q_{zz}$  the electric field gradient;  $\tau_c$  the correlation time; and  $I$  the spin quantum number.

It should also be taken into account that while the  $^1\text{H}$  NMR chemical shift is dominated by the diamagnetic term, heavier nuclei chemical shifts are generally dominated by the paramagnetic term. In **Tables 1** and **2** a summary of the NMR properties of most relevant spins  $1/2$  nuclei and spins quadrupolar nuclei, respectively, are reported.

Much of the chemical information in NMR spectra arises from chemical shifts. A decrease in atomic electron density increases the deshielding, i.e., an increase in shielding results in a decrease in the chemical shift,  $\delta$ , i.e., in a shift upfield, i.e., to less positive/more negative  $\delta$  values. Several factors, such as coordination number, oxidation state, geometry, and electronegativity of substituents, influence the shielding of the nucleus and hence the chemical shift in organometallic complexes (**Table 3**). It is very difficult to find general rules for the chemical shifts of nuclei in organometallic compounds since many interdependent factors are often involved. Shifts can be very large, up to 20 000 ppm, in metal complexes, often due to strong interaction of metal electrons with the ligands. The geometric factors can make otherwise equivalent nuclei distinct: in  $\text{Fe}_3(\text{CO})_{12}$  (**Figure 1**) the two bridging carbons will be distinct from the 10 terminal CO ligands and the terminal carbonyls on  $\text{Fe}^1$  will be different from those on  $\text{Fe}^2$ . So the  $^{13}\text{C}$  NMR spectrum will exhibit different signals for the distinct terminal CO

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy is one of the most powerful instruments in determining the structure and properties of an organometallic compound because of the sensitivity of the chemical shift to difference in geometry. Also, the term ‘organometallic’ seems suitable only for compounds having at least one carbon atom directly linked to a metal, and the scientific community uses this term also for compounds in which organic groups are bonded to nonmetallic elements such as boron, silicon, and phosphorus. In the first edition of the *Encyclopedia of Analytical Science*, the discussion of the application of NMR spectroscopy to organometallic chemistry has been mainly directed to the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, here the discussion will be addressed mainly on multinuclear NMR spectroscopy.

NMR spectra of nuclei having a spin quantum number  $I = 1/2$  are generally more easy to investigate due to a coupling behavior similar to that of  $^1\text{H}$ . However, some factors, that could make it difficult to record and assign an NMR spectrum, need to be considered: (1) isotopic abundance, (2) sensitivity, (3) nuclear quadrupole, and (4) relaxation time. For example, small molecules having nuclei  $1/2$  exhibit generally sharp lines ( $W_{1/2} = 0\text{--}10\text{ Hz}$ ), but if the nuclei interacts weakly with environments, long relaxation times, that make the detection of signals very difficult, can occur (the  $T_1$  for  $^{109}\text{Ag}$  is up to 1000 s). Nuclei having spin with  $I$  in the range  $1\text{--}9/2$  are also suitable for an NMR investigation; however, these nuclei possess a quadrupole moment (deviation from spherical charge distribution) which produces extremely short relaxation time and extremely large linewidth  $W_{1/2}$  (up to 50 Hz). If the compounds have

low molecular weight (small  $\tau_c$ ) or if the nuclei are embedded in ligand field of cubic (tetrahedral, octahedral) symmetry ( $q_{zz}$  blocked), narrow lines have been generally observed (eqn [1]).

$$W_{1/2} = \frac{(2I + 3)Q^2 q_{zz}^2 \tau_c}{I^2(2I - 1)} \quad [1]$$

where  $Q$  is the quadrupole moment;  $q_{zz}$  the electric field gradient;  $\tau_c$  the correlation time; and  $I$  the spin quantum number.

It should also be taken into account that while the  $^1\text{H}$  NMR chemical shift is dominated by the diamagnetic term, heavier nuclei chemical shifts are generally dominated by the paramagnetic term. In **Tables 1** and **2** a summary of the NMR properties of most relevant spins  $1/2$  nuclei and spins quadrupolar nuclei, respectively, are reported.

Much of the chemical information in NMR spectra arises from chemical shifts. A decrease in atomic electron density increases the deshielding, i.e., an increase in shielding results in a decrease in the chemical shift,  $\delta$ , i.e., in a shift upfield, i.e., to less positive/more negative  $\delta$  values. Several factors, such as coordination number, oxidation state, geometry, and electronegativity of substituents, influence the shielding of the nucleus and hence the chemical shift in organometallic complexes (**Table 3**). It is very difficult to find general rules for the chemical shifts of nuclei in organometallic compounds since many interdependent factors are often involved. Shifts can be very large, up to 20 000 ppm, in metal complexes, often due to strong interaction of metal electrons with the ligands. The geometric factors can make otherwise equivalent nuclei distinct: in  $\text{Fe}_3(\text{CO})_{12}$  (**Figure 1**) the two bridging carbons will be distinct from the 10 terminal CO ligands and the terminal carbonyls on  $\text{Fe}^1$  will be different from those on  $\text{Fe}^2$ . So the  $^{13}\text{C}$  NMR spectrum will exhibit different signals for the distinct terminal CO

**Table 3**  $^1\text{H}$  NMR chemical shift for selected hydride compounds

Compound	$\delta$ (ppm)		
	M=C	M=Si	M=Ge
$\text{MH}_4$	0.1	3.2	3.1
$\text{MH}_3\text{I}$	2.0	3.4	3.5
$\text{MH}_3\text{Br}$	2.5	4.2	4.5
$\text{MH}_3\text{Cl}$	2.8	4.6	5.1
$(\text{MH}_3)_2\text{O}$	3.2	4.6	5.3
$\text{MH}_3\text{F}$	4.1	4.8	5.7

**Figure 1** Different CO groups in  $\text{Fe}_3(\text{CO})_{12}$ .

environments and the bridging CO groups in  $\text{Fe}_3(\text{CO})_{12}$ . The effects of electronegativity, charge, and oxidation state can be seen in the  $^{31}\text{P}$  chemical shift of some typical phosphino-compounds. In  $\text{PPh}_3$  the  $\delta$  is 5.6 ppm, in  $\text{P}(\text{OPh})_3$  (more electronegative substituents) is 128 ppm,  $\text{PPh}_4^+$  exhibits a chemical

shift of 20.8 ppm (positive charge, whereas for  $\text{O}=\text{PPh}_3$  (+5 oxidation state)  $\delta$  is  $\sim 29$  ppm). The nature of the metal bonded to an organic group can be also an important factor in the shielding; in the series  $\text{M}(\text{CO})_6$  the shift of the carbonyl carbon decreases from 212.3 to 204.1 to 191.9 ppm on going

from  $M = \text{Cr}$  to  $\text{Mo}$  to  $\text{W}$ . These variations are due to a decreasing paramagnetic contribution to the shielding from low-lying excited states as the atomic number of  $M$  increases.

A number of factors also influences the magnitude of the coupling constants: formal hybridization of the nuclei, coordination number,  $s$ -character in the bond, electronegativity of the substituents, presence of lone pairs on the elements, oxidation state, interbond angles, *trans*-influence, etc. The magnitude of the reduced coupling constant generally increases down a group, for example,  $K_{\text{MC}}$  increases in the series  $\text{SiMe}_4$ ,  $\text{GeMe}_4$ ,  $\text{SnMe}_4$ ,  $\text{PbMe}_4$  (8.3, 18.0, 30.0, and  $39.3 \times 10^{20} \text{ NA}^{-2} \text{ m}^3$ , respectively).  $J$  ( $^{195}\text{Pt}$ ,  $^{13}\text{C}$ ) coupling constants generally increase from 450–700 Hz in platinum alkyl compounds ( $\text{sp}^3$ ) to 750–850 Hz in carbene complexes ( $\text{sp}^2$ ) to 990–2250 Hz in terminal platinum carbonyls. The coupling between platinum and phosphorus falls in the range 1050–2075 Hz for  $\text{Pt}^{\text{IV}}(\text{PR}_3)$ , 1675–5850 Hz for  $\text{Pt}^{\text{II}}(\text{PR}_3)$ , and finally 2820–9150 Hz for  $\text{Pt}^0(\text{PR}_3)$  species.

It is worth mentioning that one-bond coupling depends on  $s$ -orbital character of the bond and on the electronegativity of the nuclei, and it can be used to determine coordination number and to distinguish between axial and equatorial orientation of P-donor and fluoro groups around a metal. Two-bond couplings can give structural information, and so a relationship between  $^2J$  and bond angles is being determined for a number of compounds. The range of two-bond couplings passes through zero value, therefore the sign of the couplings must be determined in order to evaluate the magnitude of the interaction between nuclei. Finally, the three-bond couplings depend on the dihedral angles in accordance with the following equation:

$$^3J(\text{E}, \text{X}) = A \cos 2\phi + B \cos \phi + C \quad [2]$$

( $A, B, C$  = empirical constants)

NMR spectroscopy can be easily used to assign a rigid molecular structure. But not all compounds however are rigid, for example rotation can occur about the bonds in a molecule, rings can spin or change conformation and ligands can migrate between different sites. These intramolecular processes can be easily investigated by NMR and are called fluxional process. A well-investigated example in organometallic chemistry is constituted by  $(\text{Cp})_2\text{Fe}_2(\text{CO})_4$  (Figure 2) that exists as a mixture of *cis* and *trans* isomers interconverting in solution. At temperature down to  $-48^\circ\text{C}$  one single resonance is observed. At lower temperatures the signal splits into two, assignable to the *trans* and *cis* isomers (Figure 3). Analysis of changes in the NMR lineshapes with

Figure 2 *cis* and *trans* isomers of  $\text{Cp}_2\text{Fe}_2(\text{CO})_4$ .

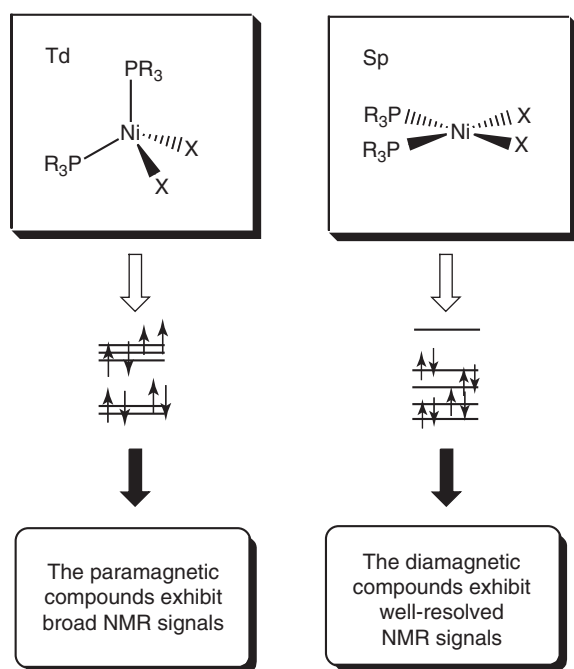

Figure 3 The signal splitting observed at low temperature for  $\text{Cp}_2\text{Fe}_2(\text{CO})_4$ .

temperature allowed to extract the rates of the fluxional processes, and in addition,  $\Delta G^\ddagger$ ,  $\Delta H^\ddagger$ , and  $\Delta S^\ddagger$  for both the *cis*–*trans* isomerization and for the equivalencing of the carbonyl ligands and then to individuate the (concerted) mechanism. Coordination number isomerization can be also investigated: for example, two geometries are possible for species such as  $\text{Ni}(\text{PR}_3)_2\text{Cl}_2$ , tetrahedral, or square-planar

**Figure 4** Diamagnetic and paramagnetic  $\text{Ni}(\text{PR}_3)_2\text{Cl}_2$  compounds.

**Figure 5** The migration of the metal fragment in  $(\eta^4\text{-cyclooctatetraenyl})\text{Fe}(\text{CO})_2(\text{CN}'\text{Pr})$ .

(Figure 4). In a tetrahedral coordination environment the compound is paramagnetic and exhibits broad NMR signals, whereas the square-planar species are diamagnetic and exhibit well-resolved NMR signals. Dynamic processes involving polyene and polyenyl ligands such as cyclopentadiene, benzene, cycloheptatriene have been widely investigated since these molecules may spin about the metal to ligand axis or may contain free olefinic bonds allowing the possibility of exchange between the free and bound carbon-carbon double bonds. We can, for example, consider the migration of the metal fragment around the  $\eta^4\text{-cyclooctatetraenyl}$  (cot) group in  $[(\eta^4\text{-cot})\text{Fe}(\text{CO})_2(\text{CN}'\text{Pr})]$  (Figure 5). Several migration pathways are possible, for example, a stepwise migration by [1,2] shifts or migration by [1,3], [1,4], [1,5] shifts, the latter being predicted by the Woodward-Hoffmann rules. This has been confirmed by saturating the resonance of a specific carbon atom in the cot ligand. As the metal fragment migrates around

**Figure 6** Excitation at carbon 2' in  $[\eta^4\text{-cyclooctatetraenyl}]\text{Fe}(\text{CO})_2(\text{CN}'\text{Pr})$  (bottom spectrum) is transferred to carbons 1, 3, and 3' ([1,5] sigmatropic shifts). (Reproduced with permission from The Royal Society of Chemistry.)

the polyenyl ligand, we can identify the sites visited by the excited carbon by following the appearance of the excitation (Figure 6). The initial saturation, which appears as negative NMR intensity at  $\text{C}^1$  moves initially to  $\text{C}^2$ ,  $\text{C}^3$ , and  $\text{C}^4$ , consistent only with the occurrence of a [1,5] migration pathway.

## The Alkali and Alkaline Earth Metals

Lithium, beryllium, and magnesium are the only members exhibiting a covalent chemistry. All the elements of this group have nuclei with quadrupole moments, and for this reason high-resolution NMR spectra of most of these nuclei exhibit severe line broadening. Notable exceptions are  $^9\text{Be}$ ,  $^{133}\text{Cs}$ , and the lithium isotopes  $^6\text{Li}$  and  $^7\text{Li}$ . The former has been the nuclide of choice for the study of organolithium compounds. The lithium chemical shifts of alkyl-lithium compounds seem to be determined completely by neighbor anisotropic effects.  $^{13}\text{C}$  and  $^7\text{Li}$  NMR are ideal methods for studying the degree of aggregation of alkyl-lithium compounds and also for the investigation of exchanges occurring between aggregates. Solvent effects are generally important: in fact solvating power affects the polarity of  $\text{Li-C}$  bond and then influences the association degree. In Figure 7 lithium chemical shifts are summarized, whereas selected coupling constant values are reported in Table 4. The  $\delta(\text{Li})$  covers a small range

**Figure 7** Selected  $\delta(^7\text{Li})$  chemical shifts for organolithium compounds.

**Table 4** Selected coupling constants involving lithium nuclei

Compound	$^1J(^6\text{Li}-^{13}\text{C})$ (Hz)	$^1J(^7\text{Li}-^{13}\text{C})$ (Hz)
(MeLi) <sub>4</sub>		14.5–15
( <sup>n</sup> BuLi) <sub>4</sub>		14
( <sup>n</sup> BuLi) <sub>4</sub>		10–14
(Br <sub>3</sub> CLi) <sub>4</sub>		43
<sup>13</sup> CH <sub>3</sub> Br <sub>2</sub> <sup>13</sup> CLi		45
( <sup>n</sup> PrLi) <sub>6</sub>	3.35	
( <sup>n</sup> PrLi) <sub>8</sub>	2.48	
( <sup>n</sup> PrLi) <sub>9</sub>	2.22	

(10 ppm) and in particular lithium covalent compounds appear at low field (2 ppm range). The detection of coupling constants between carbon and lithium indicate the presence of a covalent bond. For example the <sup>13</sup>C NMR spectrum of (<sup>n</sup>BuLi)<sub>4</sub> in ether indicates coupling of <sup>13</sup>C with three equivalent lithiums, the  $^1J(^{13}\text{C}, ^7\text{Li})$  values being 14 Hz at  $-70^\circ\text{C}$ , whereas in the case of (<sup>t</sup>BuLi)<sub>4</sub> in hydrocarbon solvents, the <sup>13</sup>C NMR spectrum indicates coupling of the  $\alpha$ -carbon with four equivalent lithiums [ $^1J(^{13}\text{C}, ^7\text{Li}) = 10\text{--}11$  Hz].

Very recently an isotopic finger print method which rests on deuterium-induced isotope shifts for <sup>6</sup>Li resonances has been proposed by Günther and exemplified with applications from the aggregation behavior of cyclopropyllithium systems and mixed aggregates formation between methyllithium and lithium salts. By using one- and two-dimensional NMR experiments based on scalar spin–spin coupling and nuclear overhauser effects the structural aspects associated with benzyllithium and the formation of polylithium systems by lithium reduction of biphenylenes have been discussed.

NMR studies on organoberyllium compounds are more limited, cyclopentadienyl (Cp) beryllium species being generally the most investigated. For example <sup>9</sup>Be resonance for CpBeMe and CpBeCl have been reported and compared with those found

**Table 5** <sup>9</sup>Be NMR parameters of selected organometallic compounds

Compound	Solvent	$\delta(^9\text{Be})^a$ (ppm)	$W_{1/2}$ (Hz)

<sup>a</sup>With reference to  $\text{Be}(\text{H}_2\text{O})_4^{2+}$ .

for beryllium complexes. Selected values of <sup>9</sup>Be chemical shifts are reported in Table 5. The great shielding of the beryllium nucleus found in Cp species has been assigned to strong ring current effects. Some beryllboranes have been recently investigated with <sup>9</sup>Be. In CpBeBH<sub>4</sub>, coupling is observed of beryllium to boron and hydrogen of the BH<sub>4</sub> group. It has been also proposed that coordination number has great effect on  $\delta(^9\text{Be})$ , four-coordinate beryllium species being generally at higher field with respect to three-coordinate compounds. A variable NMR temperature study of Cp<sub>2</sub>Be has measured the barrier height between the two equivalent potential wells for a pure pentahapto and a slip structure. The Cp multiplet fine structure found in the NMR spectrum of CpBePh suggests a  $\pi$ -complex structure or a fast migration of the PhBe moiety around the Cp ring. It is worth noting that <sup>13</sup>C–<sup>9</sup>Be coupling was not observed for CpBePh, it was for CpBeBr.

The <sup>25</sup>Mg NMR area has been scarcely explored, however, some <sup>25</sup>Mg NMR parameters (Table 6)

**Table 6**  $^{25}\text{Mg}$  parameters of selected magnesium compounds<sup>a</sup>

have been detected for a number of organomagnesium compounds  $\text{R}_2\text{Mg}$ ,  $\text{RMgX}$  ( $\text{R}$  = alkyl, aryl, allyl, Cp,  $\text{X}$  = halide) and for their adducts with Lewis bases. Ranges of  $^{25}\text{Mg}$  chemical shifts for a number of organomagnesium compounds are reported in Figure 8. It has been shown that the  $^{25}\text{Mg}$  NMR spectra for Grignard reagents depend on concentration and temperature.

## Boron

In the case of boron we have the choice between two nuclei,  $^{10}\text{B}$  and  $^{11}\text{B}$ , the former having higher sensitivity and showing no severe line-broadening problems, although having quadrupolar nucleus. The currently accepted chemical shift standard is  $[\text{BF}_3(\text{OEt}_2)]$ . Ranges of  $^{11}\text{B}$  chemical shift for selected bonding environments are given in Figure 9. The total  $^{11}\text{B}$  shielding range covers ~200 ppm. It has been found that the shielding range for four-coordinate  $\text{sp}^3$  species are generally several tens of parts per million to higher field of the nearest equivalent three-coordinate species which have generally an  $\text{sp}^2$

trigonal boron bonding environment. This fact can be employed for the assignment of structures and coordination number to nonpolyhedra boron compounds. This also means that the addition of a ligand or base to the empty p-orbital on boron results in an upfield shift as compared to the tricoordinate borane. The chemical shift is dependent on the strength of the coordination complex, with the stronger complexes shifted to higher field. Borane dimers are also found upfield from the free monomer and may show a more complex coupled spectra due to the presence of both terminal and bridging hydrogens coupling to the boron.

Selected couplings for trigonal and tetrahedral compounds are given in Table 7. One-bond couplings are dominated by the Fermi contact mechanism that means a dependence on hybridization at boron. The coupled  $^{11}\text{B}$  NMR spectra generally show a B-H coupling, unless there is a fast exchange of the hydrogens on the NMR timescale. The chemical shifts of the trivalent organoboranes having a B-H bond are more variable than that of the trialkylboranes, and are dependent on the structure of the organic group present. The trialkylboranes are found in a narrow low-field region, 83–93 ppm, the chemical shifts being widely independent of the structure of the alkyl group. Substitution at the  $\alpha$ -carbon,  $\text{R}_2\text{B}-\text{CH}_2-\text{X}$  with  $\text{X} = \text{N}_3$ , OH,  $\text{NH}_2$ , Cl, Br, Ph, Vi (Vi = vinyl) results in an upfield shift of the borane, an effect that can be assigned to inter- or intramolecular effects of the lone electron pair with the empty p-orbital on the boron or a neighboring group anisotropic effect.

Polyhedral boron-containing compounds are the most investigated species: one-bond couplings to exo-terminal protons  $^1J(^{11}\text{B}, ^1\text{H})$  are typically in the

**Figure 9** Selected  $\delta(^{11}\text{B})$  chemical shifts for organoboron compounds.

**Table 7** Selected coupling constants  $^1J(^{11}\text{B}, \text{X})$  for trigonal and tetrahedral boron compounds

Compound	X	$^1J(^{11}\text{B}, \text{X})$ (Hz)

range 120–170 Hz, consistent with  $sp$  hybridization of an exo-bond at boron on the basis of  $sp^3$  hybridization for  $[\text{BH}_4]^-$  which has  $^1J(^{11}\text{B}, ^1\text{H}) \sim 80$  Hz.

## Aluminum, Gallium, and Thallium

$^{27}\text{Al}$  is a high sensitivity nucleus that yields broad lines (quadrupole moment of 5/2) over a moderate chemical shift range. The main use is to determine the presence of aluminum or the number of different sites that it occupies. Hexacoordinate aluminum resonates between 0 and 100 ppm, while tetracoordinate aluminum can resonate between 200 and -200 ppm. The standard usually used is  $\text{AlCl}_3$  ( $1 \text{ mol l}^{-1}$  in  $\text{D}_2\text{O}$ ).  $^{27}\text{Al}$  NMR can be used to indicate the aggregation degree of organoaluminum compounds. The NMR spectrum of the 1:1 complex

of  $\text{Me}_3\text{Al}$  and  $N,N$ -dimethylethylene diamine in toluene exhibits a single resonance downfield shifted (177.1) with respect to that of  $\text{Me}_3\text{Al}$  (154 ppm). It has been proposed that the 1:1 adduct may exist as dimeric or oligomeric complex, as usually observed with many organoaluminum complexes. A range of  $^{27}\text{Al}$  NMR spectra of alkylaluminum compounds and their oxo-derivatives, recently measured exhibit narrow linewidths, the shift of which depend only upon the coordination number of the Al, though the alkyl ligands cause a marked downfield shift. The dimer  $[\text{Me}_2\text{Al} \dots \gamma \text{ picoline}]_2$  gives a resonance at 44.4 ppm, remarkably to high field of monomeric  $\text{Me}_3\text{AlNC}_5\text{H}_4\text{Me}$ , which is found at 174.7 ppm.  $[\text{AlH}_4]^-$  has been studied in a variety of systems, the Al-H coupling constant was found to be somewhat larger than early measurements had indicated, at  $\sim 170$  Hz. The  $\delta(^{27}\text{Al})$  in  $[\text{AlH}_4]^-$  is slightly dependent on the nature of the cation.

The coupling constants have been determined between  $^{27}\text{Al}$  and  $^{13}\text{C}$  or  $^1\text{H}$  in  $[\text{AlMe}_4]^-$  and in  $[\text{AlEt}_4]^-$  and ion-pairing detected. A few further studies have described the aluminum borohydride system. Shifts and coupling constants are recorded for mixed alkylhydride-borohydrides and their adducts. A chart showing the main features of  $^{27}\text{Al}$  chemical shift variation is reported in Figure 10.

Gallium has two magnetically active isotopes,  $^{69}\text{Ga}$  and  $^{71}\text{Ga}$ . The least abundant  $^{71}\text{Ga}$  is the one preferred for NMR because of its higher receptivity and slightly less efficient quadrupolar relaxation. Gallium-hydrogen spin-spin coupling has been observed in  $[\text{GaH}_4]^-$  anion, the chemical shift being 110 ppm. The chemical shift range for hydride compounds is  $\sim 5.7$  times greater for  $^{71}\text{Ga}$  than for  $^{27}\text{Al}$ . The influence of additional ligands is also different for the two elements in the two groups of compounds: in octahedral complexes the smaller  $\text{Al}^{3+}$  brings about greater steric crowding of the ligand atoms, whereas there is no such crowding in the tetrahedral complexes.

Figure 10 Trend of  $\delta(^{27}\text{Al})$  chemical shifts.

Figure 11 Selected examples of  $\delta(^{13}\text{C})$  chemical shifts.

The  $^{205}\text{Tl}$  chemical shifts of organothallium (III) compounds cover a range of over 2000 ppm and they display solvent dependence, although not as striking as that of Tl (I). Solvent basicity and ion pairing contribute to the solvent dependence. It has been found that temperature produces greater changes on the  $^{205}\text{Tl}$  chemical shifts of  $\text{Me}_2\text{TlX}$  salts with respect to other factors such as solvent concentration and nature of X. Substituent changes produce large chemical shifts, for example, the difference in chemical shift between  $\text{Me}_3\text{Tl}$  and  $\text{Et}_3\text{Tl}$  is 130 ppm. The relaxation behavior of  $^{205}\text{Tl}$  has been investigated for  $\text{Me}_2\text{Tl}^+$  in solution as a function of temperature and magnetic field strength and the dominant relaxation mechanism was found to be chemical shift anisotropy.
